

Wage Risk and the Value of Job Mobility in Early Employment Careers

Kai Liu *

October 2017

Abstract

This paper shows that job mobility is a valuable channel that employed workers use to mitigate bad labor market shocks. I estimate a model of wage dynamics jointly with a dynamic model of employment and job mobility. The key feature of the model is the specification of wage shocks at the worker-firm match level, for workers can respond to these shocks by changing jobs. I find that, relative to the variance of individual-level shocks, the variance of match-level shocks is large and the consequent value of job mobility in reducing the welfare cost of these shocks is substantial, particularly for workers whose match-specific wages are low. In counterfactual analysis, I show how the value of job mobility may be affected by search costs and unemployment income.

Substantially different versions of this paper were circulated under the titles “Wage Risk, On-the-job Search and Partial Insurance” and “Wage Risk, On-the-job Search and the Value of Job Mobility”. I am grateful to Robert Moffitt and Stephen Shore for guidance and support. I would like to thank the editor, two anonymous referees, Peter Gottschalk, Hamish Low, and the participants at several seminars and conferences for helpful comments and discussions. All remaining errors are mine.

1 Introduction

Understanding how much idiosyncratic risk people face and how individuals respond to different types of risks is important for a number of reasons. There is an extensive literature analyzing individual's precautionary behavior under incomplete markets such as savings and labor supply.¹ The implications of these models depend critically on the assessment of the levels of wage risk and the persistence of the shocks.

In most papers, changes in properly defined wage residuals represent shocks and researchers rely on the autocovariance structure of these residuals to identify the magnitude of wage risks that are distinguished by persistence of the shocks.² With a few exceptions discussed below, most of the existing literature does not specify sources of wage shocks. Understanding how individuals respond to different types of risks is important, as government programs (such as unemployment insurance) often insure against specific sources of shocks to income and can have incentive impacts on individual's behavior against risks (Meghir and Pistaferri, 2011). In addition, because changes in the wage residuals are observed after individuals' choices, policy changes that affect individuals' behavior may potentially affect the residual wages and the wage risks identified therein. This makes it hard to evaluate government programs unless we understand how wage dynamics are affected by individual behavior.

This paper aims to advance our understanding of wage risk along two dimensions. First, I distinguish two types of wage shocks, one type occurring at worker-firm match level and the other occurring at individual level, which applies to all firms and matches. The decomposition of wage risk into match-specific and worker-specific wage risk is economically significant because they have very different implications to individuals' behavior and policy. For instance, contrary to shocks at individual level, negative shocks at match level do not mean permanent depreciation of an individual's general productivity and may be recovered by workers through job mobility. Second, by modeling worker's job mobility decisions in response to labor market shocks, I show the value of job mobility as a channel of response to match-level risk facing employed workers and illustrate how it may be affected by alternative policies. The model is also capable of recovering the true wage risk, defined as the wage risk facing workers prior to their job

¹Among others, see Deaton (1992); Carroll (1992); Gourinchas and Parker (2002) (precautionary savings) and Low (2005) (precautionary labor supply). See Meghir and Pistaferri (2011) for an excellent review.

²See, among others, Abowd and Card (1989); Haider (2001); Baker and Solon (2003); Meghir and Pistaferri (2004); Blundell, Pistaferri, and Preston (2008); Moffitt and Gottschalk (2012); Jensen and Shore (2015). More recently, Lochner and Shin (2014) provide nonparametric identification results for a model of wage dynamics allowing for changes in unobserved skills.

mobility choices, which may be quite different from the wage risk inferred from observed wages after job mobility.

I build and estimate a wage process jointly with a structural dynamic model of job mobility and employment. The wage process features four independent and linearly additive components: a component that is predicted by personal characteristics, an individual component, a match component, and a measurement error. The match component can be interpreted as job-specific human capital or idiosyncratic firm effect on wages.³ The match component and individual component follow parallel stochastic processes: each of them evolves from a permanent shock with a drift. Shocks therefore represent permanent deviations from the corresponding growth profile. In the structural model, both unemployed and employed workers search for outside offers with costs. Offer arrival rates depend on search intensity, which is chosen optimally by individuals. Employed workers make job mobility and employment decisions following the wage process. They also face an exogenous layoff risk. The model implies that only the match component is correlated with job mobility choices, which can be used to separately identify the match component from the individual component in the wage residuals. Similar to Topel and Ward (1992), I find strong empirical evidence that workers' mobility decisions are correlated with job-specific wage changes in the past. The strong correlation between lagged within-job wage growth and job mobility is informative of the potential important role of match-level shocks (See Section 3 for details).

The model is estimated by the Method of Simulated Moments using longitudinal data of young male workers from the 1996 panel of Survey of Income and Program Participation (SIPP). I find that wage risk at the match level accounts for the majority of the wage risk facing workers. For instance, match-level risk can explain 81.9% and 67.5% of the overall variance of wage growth, for low- and high-education men with 8 years of potential experience, respectively. Individual-level productivity risk explains no more than 5% of the overall variance of wage growth. The fact that the majority of wage risk is at worker-firm level has important implications for job mobility and wages. For instance, it implies that, for certain workers, job mobility can be an important channel to react against negative wage shocks. Match-level wages are also important in terms of explaining overall wage growth and inequality over early careers, particularly for low-education individuals and individuals with few years

³Empirically it is infeasible to distinguish pure firm effect from pure worker-firm match effect without employer-employee matched data. This term is also referred to as match-specific wages or match-level wages throughout the paper.

of potential experience. Finally, given the large fraction of match-level shocks and the relatively high rate of job mobility in early careers, the true wage risk is a few times larger than the implied wage risk ignoring match-level wage shocks.

Counterfactual analysis conducted in this paper further highlights the importance of distinguishing sources of wage shocks and modeling job mobility behavior against match-level shocks. I find that the value of job mobility in reducing the welfare cost of negative match-level shocks is substantial, particularly for workers whose match-specific wages are low. Policies that increase the value of unemployment tend to reduce the value of job mobility. Relative to job mobility, raising unemployment income alone provides relatively small reduction to the welfare cost of negative match-level shocks, and this additional value is largely crowded out when job mobility is available to respond to these shocks. Therefore, the value of unemployment benefits against match-level shocks could be overstated without accounting for endogenous job mobility response to shocks.

To the best of my knowledge, this is the first paper that studies the welfare value of job mobility as a mechanism for workers to respond to labor market shocks.⁴ The value of job mobility in this context builds upon the premise that job mobility can be affected by match-specific wage fluctuations, via changes in both reservation wages and search intensity. In a seminal paper, Topel and Ward (1992) find evidence that previous job-specific wage growth affects workers' job mobility decisions (holding the current wage and other observed characteristics fixed). However, they find this result "somewhat puzzling in light of our previous evidence that within-job wage growth approximates a random walk" (p.473). This suggests that one needs to estimate a stochastic wage process jointly with a worker's job mobility choices, which is the direction taken in this paper.

Two closely related papers, Altonji, Smith, and Vidangos (2013) and Low, Meghir, and Pistaferri (2010), make important contributions to the literature by modeling earning dynamics and employment choices jointly. Low, Meghir, and Pistaferri (2010) estimate a wage process incorporating an individual's selection process between jobs and into and out of employment. Their estimates suggest that, once job mobility decisions are controlled for, the variance of permanent shocks is much lower. This suggests that what has been identified as the permanent wage risk from a typical error component model contains

⁴The literature has pointed out several other important channels individuals use in response to labor market risk, including Low (2005) (labor supply), Kaplan (2012) (within family), Blundell and Pistaferri (2003) (means-tested program), Gruber (1997) (unemployment insurance), Low and Pistaferri (2010) (disability insurance), and Sanders (2014) and James et al. (2012) (occupational choice).

variability due to responses to shocks through job mobility. Altonji, Smith, and Vidangos (2013) construct a rich statistical model of earning dynamics from equations governing wage determination, hours of labor supply, job-to-job transition and transitions into and out of unemployment. They show that job mobility and unemployment, among other factors, play a key role in determining the variance of earnings over a career.

The current paper contributes to this line of research in a few dimensions. One important difference is that both Altonji, Smith, and Vidangos (2013) and Low, Meghir, and Pistaferri (2010) assume that the worker-firm match component of the wage does not vary over the duration of the job. Within-job wage changes are assumed independent of a worker's job mobility decision. Therefore, there is no match-specific wage risk except the unemployment risk. One key feature of the current paper is to model wage dynamics within jobs and worker's selection across jobs and into unemployment. By doing so, it distinguishes wage risk that is particular to a worker-firm match from wage risk applying to all jobs. Similarly to Altonji, Smith, and Vidangos (2013) and Low, Meghir, and Pistaferri (2010), I find that the estimated variance of permanent shocks (from canonical models) is reduced when endogenous mobility is taken into account and match value is held constant within jobs. However, incorporating a dynamic process of match within jobs yields a much higher wage risk facing workers prior to job mobility decisions, mainly from the large estimated match-level risk.

In this paper, the structural model is estimated jointly with the wage process, thereby imposing all the restrictions from the model on the evolution of the wage process. By contrast, in both Low, Meghir, and Pistaferri (2010) and Altonji, Smith, and Vidangos (2013), identification of the wage process relies on a reduced-form model of endogenous mobility decisions without imposing all the restrictions implied by a structural model. Although estimating the wage process with selection corrections implied by reduced-form equations may be attractive in many ways, welfare implications of job mobility and related counterfactual analysis are best described by a fully-estimated structural model of job mobility. Low, Meghir, and Pistaferri (2010) evaluate welfare implications of different types of risks by using the pre-estimated wage process from the reduced-form model to calibrate the remaining structural parameters in a life-cycle model of consumption, labor supply and job mobility. While the model in the current paper adds to their model in certain dimensions (such as endogenous search intensity, shocks to match quality which affects job mobility and employment decisions), it does not allow workers to save

and ignores certain public insurance programs during unemployment. Since an individual’s response to wage risk will depend partly on the availability of either self-insurance such as savings or public insurance, the welfare value of job mobility estimated in this paper is likely to be an upper bound.

A few recent papers in the structural job search literature also make important contributions to understanding wage dynamics, including Yamaguchi (2010), Postel-Vinay and Turon (2010), Bagger, Fontaine, Postel-Vinay, and Robin (2014) and Lise, Meghir, and Robin (2015).⁵ These studies use equilibrium job search model to analyze the wage dynamics implied by the model, emphasizing the role of firms and wage determination and providing insights on how productivity shocks are translated to wages. The focus of the current paper is the workers’ endogenous decisions (search intensity, job mobility, and employment) that translate the process of “offered” wage into realized wages that are consistent with the structure of the wage data. Relative to the equilibrium search models, the wage process in this paper is relatively more general, and consequently, the labor market turnover decisions feature additional heterogeneity and dynamics. For instance, in this paper, the wage process features heterogeneous worker and match productivity, each of which evolves stochastically with own shocks and drifts; the structural model also allows for endogenous search intensity and quit to unemployment following wage shocks.⁶ More importantly, besides using the model to explain wage dynamics, the current paper adds to the literature by quantifying the value of job mobility in mitigating negative match-level shocks and showing how this value may be affected by policy environment. By being agnostic to firms’ wage policies, one main limitation of the paper is that the job creation and the offered wage distribution is assumed exogenous and invariant to policy change, which may generate bias to the counterfactual analysis.

The rest of the paper proceeds as follows. Section 2 describes the wage process and the dynamic model of job mobility and employment. Section 3 presents the data and descriptive evidence that

⁵Postel-Vinay and Turon (2010) focuses on how purely transitory productivity shocks are able to transform into persistent wage shocks that are consistent with the covariance structures implied in the wage data. The key mechanisms underlying such transformation are wage renegotiations and on-the-job search. Yamaguchi (2010) estimates a model of on-the-job search with wage bargaining. He empirically explores the effect of outside option values, match quality, and human capital accumulation on the wage growth of young workers. Using employer-employee matched data, Bagger, Fontaine, Postel-Vinay, and Robin (2014) estimate an equilibrium job search model of worker careers, allowing for human capital accumulation, employer heterogeneity, and individual-level shocks. One important addition of their paper is the ability to estimate firm heterogeneity using employer-employee matched data. Lise, Meghir, and Robin (2015) develop an equilibrium model of wage determination and employment that allows for the possibility of assortative matching between workers and jobs.

⁶For instance, Postel-Vinay and Turon (2010) ignores the impact of human capital accumulation, and Bagger, Fontaine, Postel-Vinay, and Robin (2014) only allows for individual-level shocks but not match-level shocks. In both papers, transitions from employment to unemployment are assumed exogenous.

motivates this study. Section 4 discusses the estimation and identification strategy. Section 5 presents estimation results of the main structural model and contrast them to estimates from alternative models of wage processes. Section 6 discusses implications of the structural model on sources of wage risk and inequality, as well as presenting the welfare value of job mobility against match-level shocks and how it might be affected using counterfactual analysis. Section 7 concludes. Additional materials and results are provided in the Online Appendix available on the journal's website.

2 The Model

I build a dynamic model of job search, in which an individual makes choices of search intensity, job mobility and employment. The assumptions of the model are as follows. An individual i maximizes the expected present value of utility over a finite horizon, subject to a wage process specified below. At the beginning of each period (t), the individual (either unemployed or employed) chooses search intensity which then determines the rates of offer arrival. If the individual is employed, he makes the following discrete choice: move to a different job if an offer arrives, become unemployed, or stay with the current job. Worker's acceptance decision of job offers depends on the relative quality of the current match and the offered match. If the individual is unemployed, he chooses either to become employed (if an offer arrives) or remain unemployed. This Section begins by presenting the wage process. Details of the choice structure and decision rules are discussed in Section 2.2.

2.1 The Wage Process

The life-cycle wage process for the individual i employed by firm j in period t is:

$$\ln \tilde{w}_{ijt} = \ln w_{ijt} + v_{it} \tag{1}$$

$$\ln w_{ijt} = \beta_0 + a_{ijt} + u_{it} \tag{2}$$

$$a_{ijt+1} = \begin{cases} a_{ijt+1}^l, & \text{if no job change between } t \text{ and } t+1 \\ a_{ij't+1}^o, & \text{if there is job change between } t \text{ and } t+1 \end{cases}$$

$$a_{ijt+1}^l = a_{ijt} + c + \eta_{ijt+1}, \quad a_{ij't+1}^o \sim N(0, \sigma_{a_0}^2) \tag{3}$$

$$u_{it+1} = u_{it} + \delta + \zeta_{it+1} \tag{4}$$

Assume that

$$\zeta_{it} \sim N(0, \sigma_\zeta^2), \eta_{ijt} \sim N(0, \sigma_\eta^2) \quad (5)$$

$$E(v_{it}) = 0, \text{var}(v_{it}) = \sigma_v^2 \quad (6)$$

$$u_{i0} \sim N(0, \sigma_{u_0}^2) \quad (7)$$

with orthogonality between these error terms. $\ln \tilde{w}_{ijt}$ is the observed real log hourly wage for worker i employed by firm j in period t and v_{it} is a measurement error (more on the latter below). For an employed worker, the log wage residual (after taking out the constant term β_0) is decomposed into two components: an individual component u_{it} and a match component a_{ijt} between firm j and worker i . Equations (3) and (4) describe potential (or “offered”) wage in period $t + 1$, conditional on the actual wage in period t (discussed below). All parameters of the wage process are specific to the completed education level of the individual.

The individual component (u_{it}) measures the worker’s general productivity regardless of his employer. It evolves over the life-cycle from an identically and independently distributed permanent random shock ζ_{it} and a growth factor δ . $\sigma_{u_0}^2$ measures the initial heterogeneity of general productivity. The individual component corresponds to the concept of permanent wage in the literature, which is usually thought of as representing return to skill or flow from human capital. δ captures return to work experience, perhaps through differential learning ability to general skills or human capital investment.⁷

Parallel to the individual component and prior to selection between jobs, the match component follows a random walk process with a growth factor. Let a_{ijt+1}^l be the latent match at $t + 1$ prior to job mobility (“ l ” represents latent). It evolves from a growth factor (drift), c , and a permanent shock, η_{ijt} , which is identically and independently distributed across firms, workers and time. One interpretation of the match component is that it is an idiosyncratic firm effect that is complementary to individual productivity. From the perspective of human capital theory, the match component can also be regarded as job-specific human capital. The growth factor (c) can be thought of capturing return to tenure (or firm-specific human capital). The shock to the match component then represents a

⁷One plausible mechanism that links the growth in the individual-level wage component into wage growth is to assume that wages are offered based on piece-rate contracts, as in Burdett, Carrillo-Tudela, and Coles (2011) and Bagger, Fontaine, Postel-Vinay, and Robin (2014). In this case, human capital accumulation increase output (via learning-by-doing) and log wage is a linear combination of the individual human capital, worker-firm match, and contractual piece rate.

worker-firm specific permanent deviation from the mean growth rate.⁸ This would happen, for example, when in a particular year the firm does not provide enough training to enhance the worker’s firm-specific skills (negative η_{ijt}), or it adopts a new technology that is complementary to the worker’s productivity (positive η_{ijt}). In general it consists of both a pure match-specific shock and a pure firm-specific shock, although without firm level data, distinguishing between these is not feasible. More broadly, the match component can be interpreted as any factor that affects the worker’s productivity with the current firm but not after he leaves for other firms.⁹ The growth factor and permanent shocks to the match component are accumulating only over the current job tenure and will “vanish” after a job destruction. Match- and individual-specific log wage shocks are assumed to follow normal distributions with zero means and variances σ_η^2 and σ_ζ^2 , respectively.¹⁰

A job offer with match-specific wage a^o (“o” stands for “offer”) is a random draw from a stationary offer distribution. I assume that it follows a normal distribution with mean zero and variance $\sigma_{a_0}^2$. Because of the growth profile in the individual-component of wage (due to δ), the mean offered wages would be shifting with the worker’s labor market experience. Offered matches are assumed uncorrelated with the worker’s individual wage component, which implies that there is no assortative matching in the labor market.

When worker i receives an offer from firm j' at time t , prior to making a job mobility decision, the worker is perfectly informed of his general productivity (u_{it}), match-specific productivity (a_{ijt}^l) if he chooses to stay and the value of the offer ($a_{ij't}^o$).¹¹ At any time, workers have perfect information about their current match value, the expectation of future match values, and the distribution of the

⁸One interesting area to explore is to allow the growth factor to be worker-firm specific, which can generate some very interesting wage dynamics at job changes because job mobility depends on the combination of wages and its growth rate (Burdett and Coles (2010)). In the data we are unable to observe the entire wage-tenure profile for a large number of jobs (in the SIPP data the number of wage observations per person is maximum 12 periods, or 4 years). Therefore, given the censoring problem, it is difficult to estimate the effects of heterogeneous wage-tenure profile. Note that, if there is a lot of heterogeneity in the returns to tenure, then part of the match-level shocks defined in this paper may be heterogeneity and known at the time of job mobility choice. In this case, the estimated match-level risk is likely to be an upper bound.

⁹Note that the newly accepted match would be positively correlated to the old match because of selection (that workers only move towards jobs that are more productive than their current job).

¹⁰The distribution assumptions are stronger than the standard permanent-transitory decomposition in the literature, but they are necessary in order to correct for selection bias due to endogenous employment and mobility (See Section 4 for details)

¹¹I abstract from uncertainty about worker productivity and any private and public learning. For instance, Harris and Holmstrom (1982) and Farber and Gibbons (1996) explore the implications for wage dynamics of the assumptions that employers learn about the worker productivity over time and information is public; Waldman (1984) and Greenwald (1986) analyze models in which the incumbent employer has an information advantage. Farber and Gibbons’s result that employer learning induces a martingale component into the wage process (holding worker productivity is fixed) provides a structural interpretation of wage dynamics.

match component in the labor market, but information on other job locations and their associated match value must be obtained through search. I assume that none of the shocks to the u_{it} and a_{ijt} are anticipated by the worker so they represent wage uncertainty.¹²

Measurement errors are identically and independently distributed across individuals and over time. Measurement errors may also capture some transitory wage shocks at either the worker-firm match level or the person level, although they must affect wages *after* the mobility decision is made in each period.¹³ In the canonical decomposition of shocks into transitory and permanent components, transitory shocks may well be important because of unemployment spells or temporary job spells.¹⁴ In the structural model, these sources of transitory shocks are modeled explicitly through employment and job mobility decisions. For instance, for the match-level wage process, the distinction between permanent and transitory is less important; permanent match shocks, albeit permanent from the view of workers, can be transitory ex-post if job-to-job transitions occur quickly (See Section 6.1 for some evidence).

2.2 The Model of Job Mobility and Employment

Utility function. The baseline utility function is specified as follows:

$$U_{ijt} = P_{it} \ln w_{ijt} + (1 - P_{it}) \ln b \quad (8)$$

The individual's utility depends on the log wage ($\ln(w_{ijt})$) if he is working ($P_{it} = 1$). The log wage (without measurement errors) evolves subject to the stochastic process specified above. While unemployed, the worker receives a utility flow ($\ln b$) where b includes unemployment benefits.

Intertemporal Optimization Problem. The intertemporal optimization problem can be written in recursive form using value functions. All individuals begin their lives in the unemployment state and have a finite horizon denoted by T . Since the decision period is discrete, additional restrictions are placed on the timing of the events. In particular, it is assumed that the individual is only able

¹²This excludes the possibility that parts of these random shocks may be known to workers in advance. See Cunha, Heckman, and Navarro (2005).

¹³In other words, they are unrelated to job mobility and employment decisions. It is potentially interesting to allow transitory shocks to affect job mobility and employment, although this would increase the computational burden substantially. Additionally, we need to assume that workers have perfect information to distinguish transitory shocks from permanent ones.

¹⁴For instance, Gottschalk and Moffitt (1994) provide some descriptive evidence that job mobility could be the main contributor to transitory wage shocks.

to receive a job offer conditional on the current job not being displaced. Search intensity is chosen to maximize expected utility at the beginning of period t , prior to the realizations of wage shocks in period t .¹⁵ After search intensity is chosen, wage shocks are first realized and the workers make job mobility decisions based on the new wages. When the individual is displaced, he has to remain unemployed for at least one period.

Let \mathbf{S}_i denote the set of state variables summarizing the individual's permanent characteristics (such as initial heterogeneity in the wage equation). The value of nonemployment for the individual in period t is defined by

$$V_t^n(u_{it}, \mathbf{S}_i) = \ln b + \Gamma \max_{\lambda_{it+1}^n} \left\{ \lambda_{it+1}^n E \max [V_{t+1}^n(u_{it}, \mathbf{S}_i), V_{t+1}^e(a_{ijt+1}, u_{it}, \mathbf{S}_i)] \right. \\ \left. + (1 - \lambda_{it+1}^n) V_{t+1}^n(u_{it}, \mathbf{S}_i) - \phi^n(\lambda_{it+1}^n) \right\} \quad (9)$$

where Γ is the discount factor and λ_{it+1}^n is the optimal search intensity for the unemployed individual in period $t+1$, normalized to equal the job finding rate.¹⁶ In periods of nonemployment, the individual wage component is held constant (i.e. $u_{it} = u_{it+1}$).¹⁷ $V_{t+1}^e(a_{ijt+1}, u_{it}, \mathbf{S}_i)$ is the value of employment if the worker is offered a job with match productivity of a_{ijt+1} . $\phi^n(\lambda_{it}^n)$ defines search costs incurred during unemployment given the offer arrival rate λ_{it}^n . It is assumed that the function $\phi^n(\cdot)$ is strictly increasing and convex with $\phi^n(0) = 0$. The job offer is acceptable to the individual provided that $V_{t+1}^e(a_{ijt+1}, u_{it}, \mathbf{S}_i)$ is larger than $V_{t+1}^n(u_{it}, \mathbf{S}_i)$.

¹⁵This timing restriction is made to reduce computation burden for solving the value function, because we do not need to integrate out the optimal search intensity when evaluating the continuation value function (see below). It is worth keeping in mind that shocks are permanent, and therefore, the search intensity in period $t+1$ will depend on the shock in period t .

¹⁶Note that λ_{it+1}^n (and λ_{it+1}^e in the value function of employment below) is not inside the expectation operator because it is chosen prior to the realization of wage shocks in period $t+1$.

¹⁷This assumes away any exogenous depreciation of skills following job loss. Without skill depreciation, unemployment may lead to wages on reentry being lower either because of selection into unemployment (in terms of the unobservable characteristics u_{it}) or because the new job will on average have a lower match value.

The value function of employment with the firm j in period t is given by

$$\begin{aligned}
& V_t^e(a_{ijt}, u_{it}, \mathbf{S}_i) \\
&= \ln(w_{ijt}) + \Gamma \max_{\lambda_{it+1}^e} \left\{ \lambda_{it+1}^e (1 - \rho) E \max [V_{t+1}^e(a_{ijt+1}, u_{it+1}, \mathbf{S}_i), V_{t+1}^e(a_{ij't+1}, u_{it+1}, \mathbf{S}_i), V_{t+1}^n(u_{it+1}, \mathbf{S}_i)] \right. \\
&\quad + (1 - \lambda_{it+1}^e)(1 - \rho) E \max [V_{t+1}^e(a_{ijt+1}, u_{it+1}, \mathbf{S}_i), V_{t+1}^n(u_{it+1}, \mathbf{S}_i)] \\
&\quad \left. + \rho E [V_{t+1}^n(u_{it+1}, \mathbf{S}_i)] - \phi^e(\lambda_{it+1}^e) \right\} \tag{10}
\end{aligned}$$

where λ_{it+1}^e is the optimal job finding rate when the individual is employed and ρ is the exogenous layoff probability in each period. $\phi^e(\lambda_{it}^e)$ defines search costs incurred during employment given the offer arrival rate λ_{it}^e . As for the ϕ^n function, I assume $\phi^e(\cdot)$ is strictly increasing and convex and $\phi^e(0) = 0$. Note that the marginal costs of search potentially differ by employment status, reflecting differences in technology or opportunity costs between on-the-job search and search during unemployment. When the individual accepts an external offer, his match component will be the match value offered by the new firm ($a_{ij't+1}$). The dynamics of state variables a_{ijt} and u_{it} follow the wage process specified previously. For instance, if the individual continues with the same job in the next period, his wage paid by the current employer then adjusts to a new level to absorb the returns to tenure and experience, permanent shocks to the individual and match components of wages. The worker may also choose to quit to unemployment following a large negative shock to either a_{ijt} or u_{it} .

Among employed workers, the optimal search intensity, λ_{it}^e , is determined by the first-order condition¹⁸

$$\begin{aligned}
\frac{\partial \phi^e(\lambda_{it}^e)}{\partial \lambda_{it}^e} &= (1 - \rho) E \max [V_t^e(a_{ijt}, u_{it}, \mathbf{S}_i), V_t^e(a_{ij't}, u_{it}, \mathbf{S}_i), V_t^n(u_{it}, \mathbf{S}_i)] \\
&\quad - (1 - \rho) E \max [V_t^e(a_{ijt}, u_{it}, \mathbf{S}_i), V_t^n(u_{it}, \mathbf{S}_i)] \tag{11}
\end{aligned}$$

where the marginal cost of search effort is equated with the marginal benefit of search effort given by the difference between the optimized values of current job and employment when an external offer arises. Because the marginal benefit of search declines with match-level wages and the assumption of increasing marginal cost of effort (holding all else constant), the optimal search intensity declines with

¹⁸Search intensity is normalized to equal to job offer arrival rates. This normalization is necessary for estimation of the model given that search intensity is not directly observed in the data.

match-level wages while employed.

For unemployed individuals, the optimal search intensity, λ_{it}^n , is determined by the first-order condition

$$\frac{\partial \phi^n(\lambda_{it}^n)}{\partial \lambda_{it}^n} = E \max [V_t^n(u_{it}, \mathbf{S}_i), V_t^e(a_{ijt}, u_{it}, \mathbf{S}_i)] - V_t^n(u_{it}, \mathbf{S}_i) \quad (12)$$

where the marginal benefit of search effort is given by the difference between the optimized values of employment and unemployment. The incentive for unemployment search is large for individuals with high u_{it} , because the expected market wage offered relative to unemployment income is increasing in u_{it} .¹⁹ An increase in unemployment benefits (b) reduces the marginal benefit from search, thereby reducing the incentive to search for a job when unemployed. This is the moral hazard effect of unemployment benefits in this model.

Employment and Mobility Decisions. The employment decision can be characterized by a threshold reservation value where the worker is employed if the offered match value is larger than the threshold. The reservation match, $g_t(u_{it}, \mathbf{S}_i)$, is defined implicitly by:

$$V_t^n(u_{it}, \mathbf{S}_i) = V_t^e(g_t(u_{it}, \mathbf{S}_i), u_{it}, \mathbf{S}_i)$$

where the reservation match for employment depends on the individual permanent component and unobserved type of the individual. It is straightforward to show that $g_t(u_{it}, \mathbf{S}_i)$ is decreasing in u_{it} .²⁰ Therefore, it is expected that an unemployed individual with a high individual-level wage component has a shorter spell of unemployment. This condition also implies that employed workers whose individual-level wages are high have a small probability of quitting to unemployment following a negative match-level shock.

A job mobility decision can be characterized by a threshold reservation value where the worker chooses to move if the offered match is larger than the threshold. For a worker currently employed by

¹⁹Formally, Mortensen (1986) shows that the optimal search effort increases with the mean of the wage offer distribution.

²⁰Both the values of unemployment and employment are monotonically increasing in u_{it} and, for one unit change in u_{it} , the value of employment increases more than the value of unemployment.

firm j , the reservation match, $h_t(a_{ijt})$, is defined implicitly by:

$$V_t^e(a_{ijt}, u_{it}, \mathbf{S}_i) = V_t^e(h_t(a_{ijt}), u_{it}, \mathbf{S}_i)$$

For a worker of type \mathbf{S}_i and general productivity u_{it} , the worker chooses to move only if there is an offer such that $a_{ijt}^o > h_t(a_{ijt})$. In a standard model of search on the job with utility linear in the wage and an exogenous wage offer distribution, an employed worker simply accepts any wage that is higher than his current wage (which is the reservation wage). The new reservation wage after job mobility is defined by the wage at the new job (e.g. (Burdett, 1978)). In the current model, because the match-level shocks η_{ijt} are i.i.d across jobs and over time, it simply shifts permanent income and the worker does not give anything up by accepting a job with a higher match. Therefore, given that the worker maximizes the present discounted value of log wage, the implied reservation match for job mobility is simply given by setting $h_t(a_{ijt}) = a_{ijt}$.

Implications on Wage Risk. There are two implications arising from the model of job mobility. First, modeling job mobility decisions is important to identify the true wage risk. As an example, suppose the log wage consists of only the match-specific component subject to permanent shocks. Figure 1 demonstrates two possible wage dynamics for a given worker. Prior to time t , the wage is a_0 . At the beginning of period t , he suffers a permanent negative match-specific shock η , and his new wage is $a_1 = a_0 - \eta$. The permanent wage drop considered here stems from a pure idiosyncratic firm effect and does not mean a depreciation of general individual productivity. In the absence of job mobility, his wage is expected to remain at a_1 for the rest of his working life. Now, suppose a job offer valued a^o arrives at $t + 1$ (left panel of Figure 1). If the new offer is greater than his reservation match $h(a_1)$, he would switch to the new job and earn a wage rate at $a_2 = a^o$. In this case, the wage increase from a_1 to a_2 results from an endogenous job mobility decision rather than the wage shock, a point first emphasized by Low, Meghir, and Pistaferri (2010). Moreover, by changing jobs, the worker manages to turn the initial permanent wage shock(η) into one that is effectively partly transitory and partly permanent. Only for a worker who remains at a_1 for a long time is the initial shock correctly identified. The right panel of Figure 1 depicts a second match dynamic in a similar setting. The only difference is that the worker is able to locate a better job within period t . If the worker takes the job, the observed

wage rate in period t becomes a_2 , which underestimates the magnitude of true wage shocks. The variance of permanent match-level shocks, σ_η^2 , measures wage risk prior to job mobility. The observed average wage per period alone mitigates the initial wage risk facing workers, as it is combined with the worker's response to latent shocks.

The ex-post (observed) persistence of the shocks and the extent of the latent wage shocks should depend on how quickly a worker could improve his match by changing jobs. Since the probability of job changes is inversely related to the quality of the contemporaneous match, the model implies that match-specific shocks would appear more (less) persistent for workers of higher (lower) match quality. Therefore, the contribution from permanent shocks on the variance of observed wage changes should be larger for workers of higher match quality. I provide some evidence for this claim in Section 6.1 of this paper.

The second insight from the model is that, following a negative match shock, the worker's reservation match becomes lower than the reservation match without the shock. There is now a set of wage offers that are acceptable after the match-level shock which would not have been acceptable without the match-level shock. On top of that, the optimal search intensity also increases as the marginal benefit of searching for outside offers becomes greater. This is how job mobility arises as a channel of ex-post response to wage risk. The value of job mobility depends on how the match-level shock affects the worker's job mobility decision, holding the reservation wage fixed at each period. In Section 6.2, I formally define and quantify job mobility as a means of responding to shocks in the labor market.²¹ This discussion also highlights the economic importance of modeling the dynamics of the match-specific wage a_j and the person-specific wage u separately. If match quality a_j is constant within jobs, then job mobility would not be a useful channel to counteract wage shocks.

²¹This can also be thought as the insurance value of job mobility. Note that the welfare value of job mobility considered here is not the same as shutting down all job mobility, because with random job offers and on-the-job search, there is job mobility even if workers were not to move because of match shocks. See Section 6.2 for additional discussions.

3 Empirical Evidence

3.1 Data and Summary Statistics

The data set I exploit is the 1996 panel of Survey of Income and Program Participation (SIPP). It is a four-year panel comprising 12 interviews (waves). Each wave collects comprehensive information on demographics, labor market activities and types and amounts of income for each member of the household over the four-month reference period. There are two main advantages of using the SIPP. One is that it has a short recall period, making it an ideal data set to study short-term employment dynamics that are very common among young workers.²² The other advantage is that the SIPP contains a unique job identification for every job an employed worker had through the sample period. It records job specific wages and hours at each interview date (every four months), allowing researchers to obtain the precise wage changes at the time when job transitions take place. These features make it an attractive data set to study the short-term job mobility and wage dynamics.

The original SIPP 1996 panel has 3,897,177 person-month observations.²³ I exclude women, full-time students, the self-employed, the disabled, those completing fewer than nine interviews and those who are recalled by a previous employer after a separation. I trim the population whose real wage falls into the top and bottom 1% of the real wage distribution by wave. I focus on the primary job, which is defined as the job generating the most earnings in a wave. Although SIPP has monthly information on job changes and earnings, the time unit in the analysis of this paper is four months (a wave). This avoids the seam bias if we were using monthly variables. Real monthly earnings and the wage are derived by deflating the reported monthly earnings and wage by monthly US urban CPI. The reported hourly wage rate is used whenever the worker is paid by the hour. For these workers, the real wage per wave is the mean of monthly real wage over the four months. For workers who are not hourly paid, their real wages are obtained by dividing real earnings by reported hours of labor supply per wave.²⁴ Job change is identified from a change in job ID between waves. If an individual is unemployed through the wave, no job ID would be assigned.²⁵ In the first wave of SIPP, respondents are asked the starting

²²In the selected sample, if a worker is observed to change jobs in a given calendar year, 19% of them would experience multiple job changes within the same calendar year. This means that job mobility observations at annual frequency understate the extent of job-to-job transitions by about one-fifth.

²³Note that, due to attrition, not all individuals complete 12 interviews.

²⁴For each month, respondents report hours of work per week and how many weeks they worked. Monthly labor supply is calculated as hours per week \times (weeks worked/weeks in month) \times 4.33

²⁵Fujita and Moscarini (forthcoming) document a substantial amount of recall unemployment in the SIPP data (in

date of their present job. I use this information to construct correct job tenure for workers with elapsed job duration when they are first sampled.

I construct two separate panels, one consisting of low-education individuals (those with high school education) and the other including high-education individuals (those with college education). Each panel contains individuals aged between 23 and 35 who are observed for eight consecutive waves in the sample.²⁶ For this group of individuals, job mobility is most frequent and is the most important way for wage growth in early careers (Topel and Ward, 1992). The final samples consist of 938 men in the high-education sample and 755 men in the low-education sample.

Summary statistics are provided in Table 1. Table 2 reports the distribution of the total number of observed job changes in the sample. The initial life-cycle period refers to the periods of potential experience observed in the first sample period. Overall, nearly 45% of the workers switch jobs at least once in the four-year sample period. The extent of job-to-job transitions decreases monotonically with the potential experience of the individual. For instance, among the most experienced, only 30% of the individuals made at least one job change within the sample period. In contrast, the majority of the individuals who recently entered the labor market made at least one job change by the end of the sample period.

3.2 Wage Growth and Job Mobility: Descriptive Evidence

In this section, I present a set of descriptive evidence addressing the following questions: First, what is the pattern of within-job wage growth and, in particular, how common are real wage cuts? Second, what is the empirical relation between within-job wage growth and subsequent job mobility? Are workers who experience within-job wage cuts more likely to change jobs? The empirical evidence provided in

which a worker is laid off temporally and then hired back by the same firm). It is not possible to separate out recall unemployment in the SIPP panel used in this paper, because job IDs are reset by default after an entire wave (one quarter) of unemployment. Nevertheless, the overall rate of unemployment (recall and non-recall unemployment combined) for the sample of young male workers under study is low. The option of recall unemployment is perhaps more significant in equilibrium models because it directly affects firms' incentive to post vacancies (in Fujita and Moscarini (forthcoming), posting a vacancy is costly whereas recalling a previous worker is costless). From the view of individual workers, regardless of whether there is a recall, unemployment represents the same underlying phenomenon, that of workers marginal product being lower than their reservation wage.

²⁶In the SIPP data, the maximum duration that an individual appears in the panel is 4 years. We know that many 18-22 year olds with high school education would be attending college. Given that the panel is not long enough to observe the highest completed level of education for these individuals, the age range (23-35) is imposed so that people can have completed college education. In addition, the sample excludes individuals who are full-time students in any wave in the SIPP panel.

this section are useful benchmarks to evaluate the assumptions and implications of the model.

Figure 2 presents the distribution of within- and between-job wage growth. The top panel shows the real wage growth calculated as the change in log real wages every four months.²⁷ Two features of the picture are clear. First, between-job wage growth has larger variation than within-job wage growth. Second, both within-job and between-job real wage cuts are very common. Around 45% of job-to-job transitions end up with wage cuts, and about half of within-job wage growths are negative. The majority of the within-job wage cuts are small in magnitude. For instance, the median within-job real wage cut is merely 1.3% per period. There remains, however, a substantial portion of within-job wage growth showing significant drops. Among the within-job real wage cuts, 25% of those include wage declines of 12% or more between waves. Wage cuts between jobs are much greater in magnitude: the median between-job wage decline is close to 20%. The measurement error may be an important contributor, which is accounted for in the wage process and discussed later. Part of the real wage change could also be due to the stickiness of wages that are not immediately keeping up with the rising cost of living. The bottom panel of Figure 2 shows the distribution of nominal wage growth between and within jobs. Nominal wage stickiness implies less than 1 percentage point of decline in real wage growth on average, which is very small relative to the extent of wage cuts observed in the data. For instance, the mean quarterly wage growth is 2.17% if real wage is used and 2.84% if nominal wage is used.²⁸

To understand the empirical relation between wages and a worker’s subsequent mobility choice, I estimate the following regression using individuals who are employed for at least three consecutive periods:

$$M_{ijt+1} = \alpha_1 \Delta \ln w_{ijt} + \mathbf{x}'_{it} \boldsymbol{\alpha}_2 + \gamma_{ij} + \epsilon_{ijt} \quad (13)$$

where M_{ijt+1} is an indicator variable that is equal to one if an individual i employed by firm j in period t moves to a new job in period $t+1$ (and zero if the individual does not switch jobs), $\Delta \ln w_{ijt}$ is the within-job wage growth in period t and the vector \mathbf{x}_{it} includes a quadratic in worker’s age and year dummies.

²⁷Throughout this section, wage refers to real wage unless noted otherwise.

²⁸The maximum of quarterly increase in the cost of living leads to a 1.53 percent decline in real wages. Note that change in cost of living will affect both outside offers and incumbent wages and therefore it won’t explain the large between-job wage cuts relative to within-job wage cuts.

Worker-job match fixed effects are included to control for any time-invariant unobservables associated with a worker-job match. For instance, γ_{ij} may capture the effect of match-specific permanent wages or permanent wage growth on job mobility. Parameter α_1 is the estimated effect of lagged within-job wage changes on job mobility, holding all the other covariates constant. If match-level shocks affect future job mobility as implied by our model, the estimated α_1 should be negative because worker whose within-job wage growth is low should be more likely to move to another job in the following period. If within-job wage changes are completely due to measurement errors or individual-level productivity shocks, there should be zero correlation between worker’s job mobility choices and within-job wage change.

Columns (1)-(3) in Table 3 reports the estimates using a linear probability model. In column (1), equation (13) is estimated without the match fixed effects.²⁹ Columns (2) and (3) build on the specification in column (1) by adding individual fixed effects and individual-job match fixed effects, respectively. Because the mean rate of job mobility is low, as a robustness check of the linear probability model, I also perform the analysis using a fixed effects logistic regression (where the dependent variable in equation (13) becomes a logistic function of $P(M_{ijt} = 1)$). Column (4) reports the estimates from the fixed effects logit model that include the match fixed effects. For the fixed effects logit models, I report the results in coefficients, or log odds ratios, which are interpreted as the difference in the log of odd of the outcome associated with a unit change in the covariate. The standard errors are clustered at the individual level across all specifications.

I find that within-job wage changes are negatively correlated with future job mobility (column 1). For instance, a 10% decline in the current wage increases the probability of a job change in the next period by 0.34 percentage points (column 1). The negative relationship between wage growth and mobility is similar after allowing for individual fixed effects or match fixed effects (columns 2 and 3) and nonlinearity in the regression (column 4). The fixed effects logit estimate from column 4 suggest that a 10% increase in within-job wage growth decreases the log odds of job mobility by 0.098 times.³⁰

²⁹In addition to the variables included in the vector \mathbf{x}_{it} , in columns (1) and (2), I also control for the average wage paid by firm j to worker i within the job spell that is observed in the sample period. I do not control for the wage level in the immediate prior to wage change ($\ln w_{ijt-1}$) in this regression. With transitory shocks, wages are mean reverting so a low lagged wage ($\ln w_{ijt-1}$) (that is due to a negative transitory shock) is more likely to associate with a high wage growth in period t . This would generate a spurious negative relationship between wage growth and job mobility.

³⁰The sample size of the fixed effects logit regression reflects the fact that identification of the coefficients is from job spells that include at least one job change.

The negative coefficient on within-job wage growth suggests that, holding all else equal (including permanent wage, mean job-specific wage growth, worker’s age and tenure), workers who experience small within-job wage growth are more likely to change jobs in the next following period. The evidence presented above is informative of the potential important role of match-level shocks. Note that, because part of the reported wage changes is measurement error, the estimated effect of within-job wage growth is likely to be biased toward zero and the true empirical relation between wage growth and job mobility would be stronger. One of the main tasks of estimating the structural model is to identify the within-job wage variations that are due to measurement errors, match- and individual-level shocks, accounting for endogenous job mobility and employment.

4 Identification and Estimation Strategy

For each education group, the structural model of job mobility is estimated jointly with the wage process. Following Lentz (2009), the search costs are assumed to be exponential functions in offer arrival rate: $\phi^e(\lambda) = K_e \lambda^\gamma$ and $\phi^n(\lambda) = K_n \lambda^\gamma$, where $\gamma > 1$, and K_e and K_n are the search costs required to receive an offer with certainty (i.e. $\lambda = 1$) during employment and unemployment, respectively.³¹ The discount factor Γ is not estimated and held fixed at 0.97.³² In general, the flow utility of unemployment cannot be separately identified from the cost of unemployment search (Eckstein and van den Berg, 2007). The flow utility of unemployment is fixed at the value of log unemployment benefit, where the unemployment benefit is equal to 40% of the average wage in the sample (by education group).³³ The set of parameters to be estimated includes the wage equation parameters, $(\beta_0, c, \delta, \sigma_{u_0}^2, \sigma_{a_0}^2, \sigma_\eta^2, \sigma_\zeta^2, \sigma_v^2)$, and the parameters that determine the rates of offer arrival and job destruction, (K_e, K_n, γ, ρ) .

4.1 Identification

In standard error-component models of wage dynamics, the variances of permanent and transitory shocks are identified via autocovariances (Meghir and Pistaferri, 2011). In this paper, identification

³¹These parametric restrictions ensure that the search cost function are increasing and convex.

³²The annualized discount factor is $0.97^3 = 0.91$. The value of the discount factor falls within the range of values estimated from finite-horizon dynamic discrete choice models (Keane and Wolpin, 1997; Ferrall, 2012). I also numerically evaluate the sensitivity of the estimates to alternative discount factors. The slope of the objective function is small around small changes to the discount factor.

³³Shimer (2005) and Hornstein, Krusell, and Violante (2011) set unemployment benefit equal to 41% of average wage, which is equal to the average unemployment insurance replacement rates in the US.

of all the structure based on the same standard moments is not feasible when there is endogenous job mobility and employment decisions. For instance, autocovariances of wage changes conditional on remaining on the same job and autocovariances of wage changes conditional on changing jobs would not only depend on the wage process, but also on the rest of the parameters of the structural model. Given that the wage shocks in the paper affect employment and mobility decisions, the estimates of the variances of wage shocks, the worker and the match heterogeneity are biased if selection issues are ignored.

The arguments for model identification are given below. The dynamic model of job mobility can be formulated as a Roy model:

$$\ln w_{ijt} = \beta_0 + a_{ijt}^l + u_{it} + v_{it}$$

$$\ln w_{ij't} = \beta_0 + a_{ij't}^o + u_{it} + v_{it}$$

where as previously defined, $\ln w_{ijt}$ is the log wage for an individual i employed by current employer j in period t and $\ln w_{ij't}$ is the offered log wage from firm j' . The offer acceptance rule is simply based on the difference between the offered and the current match values:

$$J_{it}^* = a_{ij't}^o - a_{ijt}^l \tag{14}$$

$$J_{it} = \begin{cases} 1 & \text{if } J_{it}^* > 0 \\ 0 & \text{elsewhere} \end{cases} \tag{15}$$

$\ln w_{ijt}$ is observed when $J_{it} = 0$ and $\ln w_{ij't}$ is observed when $J_{it} = 1$. Given the distributional assumptions of the error terms laid out in Section 2, we know that a_{ijt}^l is normally distributed conditional on a_{ijt-1} (since η_{ijt} is normally distributed), with the mean of $a_{ijt-1} + c$ and variance of σ_η^2 , and $a_{ij't}^o$ is drawn from an independent normal distribution with mean zero and variance $\sigma_{a_0}^2$.³⁴ These distributional assumptions are sufficient to identify the Roy model (Heckman and Honore, 1990). Conditional on the match- and individual-level wages at the beginning of period t and search costs functions, the following moment conditions using data from period t identify the parameters:

³⁴Due to the log-normal distributional assumption, the offered wage distribution can be recovered from the truncated distribution of observed wages (which satisfies the identification condition in Flinn and Heckman (1982)).

$P(J_{it} = 1), E(\ln w_{ijt}|J_{it} = 0), E(\ln w_{ij't}|J_{it} = 1), \text{var}(\ln w_{ijt}|J_{it} = 0), \text{var}(\ln w_{ij't}|J_{it} = 1)$. This gives us five equations in five unknowns $\sigma_\zeta^2 + \sigma_v^2, \sigma_\eta^2, \sigma_{a_0}^2, c$, and $\beta_0 + \delta$. This identification argument can be applied successively until the first period, when the distribution of match- and individual-level wages can be derived analytically given the distributional assumptions.

The panel structure of the data facilitates the identification of the model. Moments based on the autocovariances of wages are used to separately identify the variance of individual-level permanent shocks (σ_ζ^2) and the variance of measurement errors (σ_v^2). Covariances of wage changes and job mobility help to identify the return to tenure separately from return to experience. For example, a high return to tenure have differential impacts on within-job wage changes ($E(\Delta \ln w_{ijt}|M_{it} = 0)$) than between-job wage changes ($E(\Delta \ln w_{ijt}|M_{it} = 1)$), whereas return to experience (δ) implies a parallel shift on wage growth regardless of mobility. The labor market friction parameters can be identified using information from wages and transition rates between labor market states (Flinn and Heckman, 1982). For instance, cost of on-the-job search (λ^e) can be identified directly from the rates of transitions between jobs. In general, neither λ^e nor λ^n affects the reservation wage for job mobility, but both will affect the reservation wage for employment. Intuitively, if the rate of employment is low, a relatively untruncated distribution of observed wages would imply a high cost of unemployment search relative to on-the-job search, while a heavily truncated distribution would imply a high individual wage component.

4.2 Estimation Strategy

The model is estimated by the Method of Simulated Moments (MSM). Each decision period in the model corresponds to one wave (four months) in the data. In each iteration in the parameter space, computation of the simulated moments consists of nested loops. In the outer loop, the value functions in the dynamic programming problem are computed backwards. In the inner loop, the moments are simulated conditional on the value functions. The presence of match- and individual- heterogeneity increases the state space. Online Appendix A describes the solution method to the value function in detail. The method uses Monte Carlo integration and an interpolation method to approximate the value function. The standard errors are computed using the formula described in Online Appendix B.

For each individual in each sample period, we observe job mobility, employment choices and log wages if the individual is employed. The empirical moments include the means of job mobility, employ-

ment, transition from employment into unemployment, and log wages in each sample period, and the covariances of job mobility and log wage between any two sample periods. Since SIPP is a short panel, it is typical that some workers have left-censored life-cycle histories when they are observed in the first wave. For these workers, their first observed wages are endogenous, which leads to an initial condition problem (Heckman, 1981). The initial condition problem is solved by simulating the model starting from the beginning of the life cycle and evaluating the moments conditional on each individual’s first observed life-cycle period τ_i .³⁵ The mean of elapsed job tenure when a worker is first observed in the sample is added to the set of moments to match.³⁶ Details of the estimation procedure are discussed in Online Appendix B.

5 Estimation Results

Table 4 reports the estimated parameters of the structural model, separately for low-education and high-education men. Relative to individual-level productivity risk, I find that wage risk at the worker-firm match level is the dominating risk facing employed workers. For instance, among low-education men, the variance of match-level shock (σ_η^2) is 0.005, whereas the variance of the person-level wage shocks is 50 times smaller and insignificant from zero ($\sigma_\zeta^2 = 0.0001$).³⁷ The relative magnitude of individual- vs. match-level shocks is further highlighted in terms of their contributions to overall wage variance in Section 6.1.

Relative to the match- and individual-level permanent shocks, the variance of measurement errors is indeed quite large. Consistent with findings from Gottschalk (2005) and Abowd and Stinson (2011), I find that a substantial quarter-to-quarter variation in wages is due to measurement errors.³⁸ Note that, even though the variance of measurement errors is large in quarterly data, its contribution to the variance of annual wage is relatively small compared to persistent shocks. When quarterly wages are

³⁵Twenty simulations per individual are conducted. The simulations prior to period τ_i are discarded so that the distribution of τ_i in the simulated sample matches the distribution in the real data.

³⁶Recall from Section 3.1 that the SIPP contains information on the starting date of a worker’s present job when he is first sampled. This information is used to construct the elapsed job tenure at the first interview date.

³⁷The relative contribution of match-level risk and individual-level risk to the overall variance of wage growth depends on the extent job mobility. In Section 6.1, I evaluate the relative importance of different types of risks in explaining the overall variance of wage growth.

³⁸As previously discussed in Section 2.1, in this paper, transitory shocks are interpreted as measurement errors. In the estimation sample, the measurement error in wages may come from two sources: from reported wages for those who are hourly paid and from reported earnings and/or hours for salary-paid workers.

aggregated to annual wage, the variance of quarterly permanent shocks will be “amplified” more than the variance of quarterly measurement errors.³⁹

The estimated returns to tenure (c) is 0.2% per period among low-education men. Among high-education men, the estimated return to tenure is slightly negative (at -0.4% per period). The small estimates of return to tenure are in line with existing estimates that are able to account for selection from job mobility and employment.⁴⁰ Relative to the return to tenure estimate, the estimated return to experience is positive and large. The return to experience is relatively higher among the high-educated than the low-educated (2.4% vs. 1.1% per period). Relative to the return to tenure, match-level shocks can generate large changes to match quality. For instance, for the low education group, a one standard deviation match-level shock is equivalent to 7.2% of the match-level wages, whereas the mean return to tenure is only 0.2% per period. Because workers are able to preserve good match shocks and move away from bad match shocks by job mobility, match-level wage shocks and job mobility alone can generate sufficient positive wage growth over time (see Section 6.1 for additional discussion).

The estimated initial heterogeneity of the individual wage component is larger than the match offer heterogeneity. This gap is particularly large among the low-education individuals, which has important implications for the sources of wage inequality (to discuss in the following section). Moreover, it also suggests that the heterogeneity of individual productivity, on top of match heterogeneity, is essential for the model to match both the extent of labor market transitions and wage dispersions.⁴¹ Among low-education men, the estimated marginal cost of unemployment search is large relative to the marginal cost of on-the-job search. This relationship is reversed among the high-education men, where the marginal cost of on-the-job search is larger than that of unemployment search. Holding the marginal benefit of search constant, the offer arrival rate among the high- (low-) education group tends to be higher (lower) during unemployment than employment.

Figures 3 and 4 report the fit of the model to the sample of low-education and high-education men,

³⁹As an illustration, in Online Appendix Section C, I show that the permanent-transitory variance ratio in annual data can be six times as high as the ratio defined using quarterly data. The approximation is based on the canonical wage process and Taylor approximation.

⁴⁰For instance, Altonji and Williams (2005) report that their preferred estimate of return to tenure for the United States is about 1 percent per annum. Note that this literature typically assumes that any shock to within-job wages is transitory and does not relate to turnover behavior. The negative return to tenure among the high-educated coincides with Nagypal (2005), who shows that a decreasing value of match quality over the job tenure is necessary to explain the high rate of job turnovers in her data.

⁴¹Bils, Chang, Kim, and Hall (2009) and Hornstein, Krusell, and Violante (2011) show that match heterogeneity alone is insufficient to produce both realistic wage dispersion and unemployment fluctuations at the same time.

respectively.⁴² The simulated outcomes exhibit a reasonably good fit to the data. The simulations capture essential features of the data including the average wage, job mobility and employment, as well as the variance and autocovariance of wage and mobility. Although the model predicts employment rate closely, it tends to overpredict the transition rate from employment to unemployment. Among low-education men, the model also tends to underpredict the rate of job mobility.

Figure 5 plots the actual and predicted distributions of within- and between-job wage growth of workers. The predicted wage growth does not include any measurement errors. Note that the conditional wage distributions are not among the set of directly targeted moments and, therefore, they provide additional evidence on the explanatory power of the model.⁴³ Overall, the model is able to predict the essential features of the wage distribution. For instance, the model correctly predicts that the distribution of within-job wage growth has much less dispersion than the distribution of between-job wage growth. Except for between-job wage growth among the high-educated, the peaks of the densities are predicted reasonably well. However, the model underpredicts the fraction of job changes with negative wage growth. Job mobility with wage cuts has been difficult to reconcile in the job-search literature because, with a stationary wage policy, the worker chooses to switch jobs only if there exists a job offering a higher wage.⁴⁴ Although the model is successful in predicting some between-job wage cuts (e.g. due to a cut in the person-component of wage or a negative latent match-level shock), the measurement error is essential to explain large wage cuts between jobs.

5.1 Evidence from Alternative Wage Processes

5.1.1 Constant match quality within jobs

What happens if shocks to the worker-firm match are ignored? This corresponds to the assumption made in Low, Meghir, and Pistaferri (2010) and Altonji, Smith, and Vidangos (2013), where the worker’s mobility choice is solely based on the value of the initial match.⁴⁵ Columns (1) and (3) of

⁴²To evaluate the fitness of the model, I simulate 20 careers for each worker in the sample. For each worker, I then keep 8 periods within each career path according to the individual’s first observed life-cycle period τ_i .

⁴³The actual distributions are based on the same data used to produce the top panel of Figure 2, except that I have disaggregated the sample by education groups for comparisons with the model predictions.

⁴⁴Postel-Vinay and Robin (2002) and Dey and Flinn (2005) rationalize between-job wage cuts through an on-the-job search with wage renegotiation between worker and current employer responding to outside offers. Hedonic models provide another explanation. Many structural estimations of search model (e.g. Wolpin (1992)) assume that observed wages contain measurement errors in order to produce positive likelihood of wage cut.

⁴⁵Online Appendix D describes this alternative wage processes. The model is estimated using the same set of moments as described in Section 4.

Table 5 present the estimated parameters when the match values are held constant within jobs, for low- and high-education men, respectively. When match-level shocks are ignored, there is a large increase in the estimated variance of individual-level permanent shocks. For instance, among high-education men, the variance of individual-level shocks increases tenfold (from 0.0002 to 0.002).⁴⁶ A large proportion of wage fluctuations that is specific to a worker-firm match has been identified as permanent shocks that persist across all jobs. In addition to the differences in the estimated individual-level productivity risk, the alternative model also has different implications in terms of the overall wage risk. In the main model, the “true” wage risk is the sum of the variance of the person- and match-level shocks. Under the alternative wage process, individual-level productivity risk is the only source of wage risk. A comparison between the two models suggest that the true wage risk is a few times larger than the wage risk implied from this alternative model. For instance, among low-education men, the true wage risk is 0.0053 ($=0.0052+0.0001$), and the individual productivity risk implied by the alternative wage process is 0.001.

Online Appendix Figures A1 and A2 show the fitness of the alternative model against the targeted moments of low-education and high-education men, respectively. Relative to the benchmark model, the alternative model fits the data less well in a few dimensions, although the alternative model also provides a reasonable overall fit to data. For instance, the alternative model fits less well for the covariance moments between job mobility and wage. For the low-education sample, the alternative model overpredicts the rate of employment. For the high-education sample, the alternative model tends to underpredict job mobility and overpredict the transition rate from employment to unemployment.

The alternative model fails to capture two important features of the data that are not among the targeted moments used in estimation. Online Appendix Figure A3 plots the actual and predicted distributions of within- and between-job wage growth of workers from the alternative wage process (without measurement errors). Compared with the predicted distribution from the benchmark model (Figure 5), the alternative model underpredicts the dispersion of within-job wage growth and between-job wage cuts. For instance, among low-education men, the benchmark model implies that 14.3% of job-job transitions are associated with a wage cut, whereas the fraction predicted by the constant match quality model is 7%. In the constant match quality model, wage cuts can only be rationalized by a

⁴⁶Note that, this estimated variance of individual-level wage shock is not directly comparable to Low, Meghir and Pistaferri (2010), where they assume that the permanent shock occurs each quarter with probability 0.25.

negative shock to individual productivity. The benchmark model can account for additional wage cuts due to negative latent match-level shocks that affect job mobility but not are reflected in the pre-mobility wages. Online Appendix Table A1 reports the data and model predictions for the (Pearson) correlation coefficients between current within-job wage growth and job mobility in the immediate period. In the data, the correlation coefficients are negative. This pattern is captured by the model including match-level shocks (and measurement errors), but not by the alternative model with constant match quality. When match quality is constant within job spells, within-job wage growth is due to measurement errors and/or individual productivity shocks, neither of which affects job mobility decisions.

5.1.2 Exogenous Wage

In columns (2) and (4) of Table 5, I estimate a canonical wage process that has been frequently used to estimate wage uncertainty in the labor economics and macroeconomics literature. In this model, wages are exogenous; there is no match-specific wage component and no selection into/out of employment and over jobs.⁴⁷ Relative to the estimated permanent individual productivity risk allowing for endogenous job mobility and employment, the variance of permanent shocks is larger (but still smaller than the true wage risk defined above). For instance, among low-education men, the canonical model implies that the variance of permanent shocks is 0.0016, whereas the alternative model accounting for endogenous job mobility implies the variance of permanent shocks being 0.001. These results are qualitatively similar to findings in Low, Meghir, and Pistaferri (2010), where they show that over half of the identified permanent wage uncertainty stems from the worker’s endogenous job mobility choice.

Online Appendix Figures A4 and A5 show the fitness of the exogenous wage model against the targeted moments of low-education and high-education men, respectively. Overall, the parsimonious model assuming exogenous wage provides a reasonable fit to the variance of autocovariance of observed wages in the data. Relative to the benchmark model, the main feature of the data that the exogenous wage model fails to capture is that the variance of log wages is relatively flat in over time in the data. Given that the permanent wage component follows a random walk, the implied variance of log wages is strongly increasing over time. Online Appendix Figure A6 plots the actual and predicted

⁴⁷Online Appendix D describes this alternative wage processes. This wage process resembles the wage process in Moffitt and Gottschalk (2012), except that the transitory shocks are assumed to be i.i.d and interpreted as measurement errors for better comparison with the benchmark model. Because job mobility and employment decision is ignored, the model is estimated using the following moments (that is a subset of moments used in estimating the full model): the variances/covariances of wages and mean wages.

distributions of within- and between-job wage growth of workers from the exogenous wage process (without measurement error). Because job mobility is not part of the model, the exogenous wage process fails to capture an essential feature of the wage distribution—that the distribution of between-job wage growth has large dispersion relative to the distribution of within-job wage growth.

6 Implications of the Model

6.1 Wage Growth, Inequality and Wage Risk in Early Careers

Using the estimated parameters in the model, I simulate 20 paths from beginning of the life cycle for each individual in the sample. I use the simulated career histories to address the following three questions. First, what are the relative contributions from the match- and the individual-level wages to overall wage growth and inequality over time? Second, what is the relative importance of different types of risks on the variance of (residual) wage growth that is typically regarded as wage risk? Third, how persistent are the (realized) match-level shocks after job mobility choices?

To address the first question, I decompose the mean and the variance of simulated population wages over the first 30 periods (10 years) of the life cycle. Wages are defined as wage residuals, abstracting from the permanent offered wage (β_0) and any measurement errors. The top panel of Figure 6 examines the age profile of mean wages, separately for low- and high-education men. The growth of the individual component ($E(u_{it})$) is due to the positive return to work experience, which is larger among the high educated than the low educated. Among low-education men, match-level wage growth is larger than individual-level wage growth in the first few years in the labor market. After 10 years into the labor market, match-level wage and individual-level wage are equally important in explaining wage growth for the low education group. For the high-education men, individual-level wage (and therefore return to experience) is the main driving force for overall wage growth for most of the early career. Given the small estimates of return to tenure, the growth in the match component ($E(a_{ijt})$) is due to job mobility as workers climb up the job ladder. The existence of match-level shocks also pushes wage to grow further, because only good shocks are kept and bad shocks could be alleviated through job changes.⁴⁸

⁴⁸Online Appendix Figure A7 shows that the cross-sectional distribution of incumbent match becomes increasingly right-skewed as job tenure increases. When the extent of job-to-job transitions decreases as workers are further up the job ladder, the growth of $E(a_{ijt})$ gradually slows down, generating a concave wage profile.

The bottom panel of Figure 6 shows the contributions from match- and individual-level wages to overall wage inequality over time. At the beginning of life, most wage inequality is from variation in individual heterogeneity (i.e. individual’s general ability). As a worker accumulates labor market experience, the contribution from the worker-firm match quickly rises as a result of the match shocks and job-to-job transitions. For instance, among low-education men, after 10 years from the beginning of life, the contribution from match-level wages eventually exceeds the contribution from the person-level wages. This implies that differences in labor market histories are an important driving force behind the increasing inequality in early careers.⁴⁹

The model also generates a set of predictions regarding the contributions of different types of risks on cross-sectional inequality. Suppose we have a set of individuals who are employed in both periods $t - 1$ and t . We can decompose the inequality of wage growth between periods $t - 1$ and t into the following four components:

$$\begin{aligned}
\text{var}(\Delta \ln w_{ijt}) &= \text{var}(\Delta a_{ijt}) + \text{var}(\zeta_{it}) \\
&= \underbrace{\text{var}(E(\Delta a_{ijt}|M_{it}))}_{\text{between group variance}} + \underbrace{\text{var}(a_{ijt} - a_{ijt-1}|M_{it} = 1)P(M_{it} = 1)}_{\text{match heterogeneity}} \\
&\quad + \underbrace{\text{var}(\eta_{ijt})P(M_{it} = 0)}_{\text{match risk}} + \underbrace{\text{var}(\zeta_{it})}_{\text{productivity risk}}
\end{aligned} \tag{16}$$

The first term, between group variance, represents heterogeneity in the conditional mean match quality with and without job mobility in period t . Match heterogeneity reflects heterogeneity in the offered match quality conditional on moving.⁵⁰ Match risk and productivity risk refer to uncertainty to match- and individual-level wage component. The contribution from productivity risk is assumed invariant to job mobility and hence independent from worker’s match-level wages in period $t - 1$. The relative importance of match heterogeneity and match risk depends on the probability of job mobility and henceforth worker’s reservation wage.⁵¹

Table 6 compares the contributions from different wage components on the overall variance of wage

⁴⁹This result is similar to recent findings from Huggett, Ventura, and Yaron (2011), who argue that policies aiming at improving worker-firm matches are at least equally important as education policies aiming to improve initial conditions.

⁵⁰As correctly noted in Low, Meghir, and Pistaferri (2010), part of this term also reflects uncertainty from outside offer draws conditional on current match quality.

⁵¹The discussion in this section focuses on wage inequality without measurement errors. Measurement errors contribute significantly to the variance of observed quarterly wage changes, although the contribution declines for the inequality of annual wage changes (see Online Appendix C for a related discussion).

growth for both low-education and high-education women. The results are reported at the end of year 1 (period 3), year 4 (period 12) and year 8 (period 24) of the model. At the end of year 1 of the model, about half of the variation of wage growth is due to match-level wage shocks. The remaining half is mainly explained by match heterogeneity and between-group variance. For instance, at the end of year 1, between-group variance accounts for 19.8% and 27.3% of the wage variance among low- and high-education men, respectively. Individual-level productivity risk explains no more than 5% of the overall variance of wage growth. As individuals gain labor market experiences, the wage variance explained by the between-group variance declines significantly. The contribution from match heterogeneity also declines substantially as a result of declining rate of job mobility. In the meantime, the contribution from match-level risk increases substantially. In order of importance, the key factors explaining the variance of wage growth at the end of year 8 of the model are match-level risk, match heterogeneity, between-group variance, and individual-level productivity risk. At the end of year 8, match-level risk can explain 81.9% of the overall wage variance for low-education men and 67.5% of the overall wage variance for high-education men.

In the model, individual productivity shocks are permanent but the “ex-post” persistence of match-level shocks depends on the rate of job mobility. It is possible to assess the “ex-post” persistence of match-level shocks. A primitive analysis is provided as follows. Suppose a fraction of a match-level shock is permanent and remaining fraction of the match-level shock is an i.i.d transitory shock. Let $\Delta a_{it} \equiv a_{it} - a_{it-1} = \theta \eta_{it} + (1 - \theta) \Delta \eta_{it}$ be the “realized” change in match-level wages between t and $t - 1$, where θ is the fraction of the match-level shock that is ex-post permanent and, correspondingly, $1 - \theta$ is the fraction that is ex-post transitory. Then, the variance of match-level wage change is given by $var(\Delta a_{it}) = ((1 - \theta)^2 + 1) \sigma_\eta^2$. The fraction of match-level shocks that is permanent, θ , is given by $1 - \sqrt{\frac{var(\Delta a_{it})}{\sigma_\eta^2}} - 1$. Note that, in the extreme case where there is no job mobility, $\theta = 1$ and all of the changes in match-level wage are permanent.

I find that, at the beginning of careers, match-level shocks are mostly transitory as workers are able to find better outside offers quickly. A large fraction of match-level shocks are permanent for workers with additional years of experience. Among low-education men, the fractions of match-level shocks that are ex-post permanent at the end of year 2 (period 6), year 4 (period 12) and year 8 (period 24) are 39.1%, 56.8% and 69.3%, respectively. Among high-education men, the fractions of match-level shocks

that are ex-post permanent at the end of year 2 (period 6), year 4 (period 12) and year 8 (period 24) are 14.7%, 37.3% and 46.3%, respectively.

6.2 Value of Job Mobility against Match-level Shocks

6.2.1 Definition and Measurement

Consider an individual i employed by firm j at the beginning of period t , just before the realization of the wage shock (η_{ijt}, ζ_{it}) for that period. Let $\tilde{a}_{ijt} (\equiv a_{ijt-1} + c)$ be the match-specific component prior to the match-level wage shock in period t . I measure the value of job mobility as the degree to which the individual is indifferent between particular realizations of a negative match-level shock. I define the difference in continuation values due to the match-level shock as

$$\Delta_{it} = V_t^e(\tilde{a}_{ijt}, u_{it}, \mathbf{S}_i) - E_\eta(V_t^e(a_{ijt}, u_{it}, \mathbf{S}_i | \eta_{ijt} < 0)) \quad (17)$$

where $V_t^e(\tilde{a}_{ijt}, u_{it}, \mathbf{S}_i)$ is the continuation value without any negative match-level shock, and $E_\eta(V_t^e(a_{ijt}, u_{it}, \mathbf{S}_i | \eta_{ijt} < 0))$ is the mean continuation value following negative match-level shocks. Δ_{it} defines the welfare loss from the match-level wage shock. If $\Delta_{it} = 0$, then the individual is indifferent between the state when the match-level shock arrives and when there is no match-level shock.⁵²

To quantify the value of job mobility, I consider a modification to the environment that removes job mobility as a channel of responding to the match-level wage shocks. Under the counterfactual environment, the difference in continuation values due to match-level shocks is given by

$$\widehat{\Delta}_{it} = \widehat{V}_t^e(\tilde{a}_{ijt}, u_{it}, \mathbf{S}_i) - E_\eta(\widehat{V}_t^e(a_{ijt}, u_{it}, \mathbf{S}_i | \eta_{ijt} < 0)) \quad (18)$$

where \widehat{V}_t^e denotes the continuation value in the counterfactual environment. The counterfactual environment disallows job mobility to respond to match-level shocks by holding the reservation wage for job mobility at the level before the match-level shock is realized in every period of the model. Formally, in every period t and for any draw of match-level shocks (η_{ijt}) and outside offers $(a_{ij't}^o)$, the transition

⁵²Relative to match-level wage shocks, I find that individual-level wage shocks has very small welfare impacts on average. For this group of young male workers, the size of the individual-level wage shocks appears to be too small to have any sizable impact on workers' behavior and welfare.

probability of match-level wages under the main model is given by

$$f_t(a_{ijt}|\eta_{ijt}, a_{ijt-1}) = f_t(a_{ijt}|M_{it}, \eta_{ijt}, a_{ijt-1})h_t(M_{it}|\eta_{ijt}, a_{ijt-1}) \quad (19)$$

where job mobility (M_{it}) can respond to match-level shocks (η_{ijt}) via the h density. When job mobility is removed as a channel of responding to the match-level wage shocks, the counterfactual distribution, denoted by \hat{f} , is given by

$$\hat{f}_t(a_{ijt}|\eta_{ijt}, a_{ijt-1}) = f_t(a_{ijt}|M_{it}, \eta_{ijt}, a_{ijt-1})h_t(M_{it}|0, a_{ijt-1}) \quad (20)$$

where the likelihood of job mobility (the h density) is evaluated holding η_{ijt} at zero. The density function \hat{f} is used to define the value function in the counterfactual environment in each period.⁵³

In the model, job mobility may reduce the welfare cost of match-level shocks via two inter-related channels. Following the negative match shock, the worker's reservation match becomes lower than the reservation match without the shock. There is a set of wage offers that are acceptable after the match-level shock, which would not have been acceptable without the match-level shock. In the meantime, following negative match-level shocks, search intensity would increase to take advantage of the increasing marginal benefit from job mobility. This increases the rate of offer arrival and further strengthen the value of job mobility as a channel to reduce the welfare cost of match-level shocks. The counterfactual environment thereby disallows job mobility to respond to match-level shocks falling in this range whereas keeping the wage distribution conditional on job mobility unchanged.

The value of job mobility as a channel against negative match-level shocks can be defined as

$$\xi_{it} = 1 - \frac{\Delta_{it}}{\widehat{\Delta_{it}}} \quad (21)$$

where ξ_{it} is the proportional decrease to the average cost of negative match-level shocks due to the option of job mobility. Note that ξ_{it} is heterogenous across workers because it depends on both match- and

⁵³In this paper, the value of job mobility is defined in terms of how job mobility affects the welfare loss from the match-level wage shock, not how job mobility improves the overall level of welfare. Even without match-level shocks, the individual would be worse off if job mobility is removed because the individual has to forego outside offers that may provide improvement in match quality. The primary focus of the paper is not the value of job mobility, per se, but the component of that value that is related to the welfare effects of match-level wage shocks. This is similar to what has been used in the literature to define the “insurance” value of individual actions against different types of shocks (e.g. Kaplan (2012)).

individual-level wages. If ξ_{it} is very close to zero, then the welfare loss from the negative match shock is almost identical whether job mobility is allowed or not. In this case, job mobility is not a valuable channel against the match-level shock. If ξ_{it} is close to one, then the welfare loss from the negative match shock is small when job mobility is allowed (relative to the welfare loss when job mobility is disallowed), which implies that job mobility is a highly valuable channel against the match-level shock.

6.2.2 The Value of Job Mobility

I use the estimated model to calculate the value of job mobility for individuals with four different combinations of the individual- and match-level wages. I consider two types of individuals, u^H (large individual-level wage) and u^L (small individual-level wage), who are matched to jobs with high (a^H) and low match quality (a^L).⁵⁴ Column (1) of Table 7 shows the value of job mobility (ξ_{it}), defined in terms of how much the average cost of match-level shocks is reduced due to the availability of job mobility (equation (21)). I find that job mobility can reduce the average cost of a match-level shock, particularly for individuals whose match-level wages are low. For instance, for a low-education individual with high individual-level wage but matched to a job with low match-level wage, job mobility can reduce the average welfare cost of negative match-level shocks by as much as 63.8%. By contrast, if the same individual worked for a job with a high match-level wage, then the value of job mobility reduces substantially to 10.4%. Relative to workers whose match quality is high, workers located in the bottom of the match quality distribution respond more to a given negative match shock.⁵⁵

Holding match quality fixed, I find that workers whose individual productivity is high benefit more from job mobility (in terms of reducing the average welfare cost of negative match-level shocks) than workers whose individual productivity is low. For instance, among low-educated workers with the same match quality at a^L , the values of job mobility are 63.8% and 58.1% for workers with high- and low-levels of individual productivity, respectively. The reason underlying this difference is because of different reservation match values for employment: workers with high individual productivity have lower reservation match quality for employment than workers with low individual productivity. For a

⁵⁴The value of job mobility is computed at the end of year 4 (period 12) in the model. The high- and low-values of individual- and match-level wages are defined at the 90th and 10th percentile of the corresponding distributions in period 12, respectively.

⁵⁵Formally, this conclusion depends on the relative position of the match quality distribution and the offered match distribution. For instance, Online Appendix Figure A7 shows, for individuals who are already at the top of the job ladder, job mobility could be useful only for mitigating large negative match-level shocks. Endogenous search intensity would strengthen the reaction to negative match-level shocks.

given large and negative match-level shock, workers with low individual productivity are more likely to quit for unemployment, thereby reducing the value of job mobility in reacting to this shock.

6.2.3 The Role of Search Costs and Unemployment Benefits

Columns (2) to (4) of Table 7 report how the value of job mobility might be affected by changes in the model environment. I focus on the following three scenarios: (i) a one-third increase in the replacement rate of unemployment benefits from 40% to 52% (column 2); (ii) a decrease in the marginal cost of unemployment search (column 3) and (iii) a reduction in the marginal cost of on-the-job search (column 4).⁵⁶

Both unemployment and job mobility are potential channels that workers may use to alleviate negative match-level shocks. I find that policies that make unemployment more attractive reduces the value of job mobility. For instance, the expansion of unemployment benefits reduces the value of job mobility (column 2). The reduction is particularly large for the group of workers with low-individual productivity and low match quality. Among low-education men, the value of job mobility for these workers is reduced by 0.107, or 18.3% relative to the initial level. Among high-education men, the value of job mobility for these workers is reduced by 0.118, or 20.4% relative to the initial level. A reduction in the cost of unemployment search has the same qualitative effects on the value of job mobility (column 3), although the effects are small relative to the effects of the expansion in unemployment benefits. Finally, column 4 shows that a decrease in the cost of on-the-job search increases the value of job mobility and the increase is relatively more pronounced for individuals with low match quality.

To further explore the interaction between job mobility and unemployment benefit in alleviating match-level shocks, Table 8 reports the welfare cost of match-level shocks under four different model environments. The baseline column (column 1) reports the welfare cost of match-level shocks where job mobility is removed from a channel of responding to the match-level wage shocks ($\widehat{\Delta}_{it}$). Columns (2) and (3) report the differential welfare cost after allowing for job mobility to respond to match-level shocks ($\Delta_{it} - \widehat{\Delta}_{it}$) and raising unemployment income, respectively. Column (4) reports the interaction effects from adding both job mobility and raising unemployment income simultaneously. I find that an increase in unemployment income alone can also reduce the welfare cost of match-level shocks without

⁵⁶The reduction in the marginal cost of search is set such that the one-third increase in UI benefits combined with the reduction in search costs implies a constant net flow utility when the rate of offer arrival is equal to one.

job mobility (column 3). However, relative to job mobility (column 2), the reduction in the welfare cost tends to be small. Therefore, unemployment is a useful channel to alleviate negative match-level shocks but it is less valuable when compared to job mobility. The positive interaction effects between job mobility and unemployment (column 4) implies that job mobility is less valuable when there is higher unemployment income (adding columns 2 and 4) and raising unemployment income offers less welfare gains in the presence of job mobility (adding columns 3 and 4). In fact, the value of higher unemployment income is largely crowded out by job mobility (adding columns 3 and 4). Therefore, the value of unemployment benefits against match-level shocks could be overstated without accounting for endogenous job mobility response to shocks.⁵⁷

This exercise, albeit speculative (e.g. because the partial equilibrium nature of the model), highlights the importance of distinguishing sources of wage shocks and modeling job mobility behavior against match-level wage shocks. Policies that make unemployment benefits more generous increase the reservation match quality for employment. Consequently, workers are incentivized to switch from using job mobility to unemployment as a channel to react to a certain range of match-level shocks. The crowding-out effects are especially pronounced among the group of workers with low-individual productivity and low match quality.⁵⁸ Relative to offering more generous unemployment income, policies that subsidize the cost of unemployment search have a relatively minor impact on the value of job mobility.

7 Conclusion

In this paper, I estimated a dynamic structural model of job mobility and employment jointly with a stochastic wage process. I considered two sources of wage shocks, shocks at the worker-firm match level and shocks at the individual level that persist across jobs, and modeled their effects on dynamic individual behaviors such as employment, job mobility and job search efforts. The estimation results suggest that wage risk at match level is the dominating type of risk facing employed individuals. In order of importance, the key factors explaining the variance of wage growth at the end of year 8

⁵⁷Unemployment benefits still have welfare value of insuring against other type of risk such as job destruction. Job mobility is not a channel that workers can use to react upon layoff.

⁵⁸For this group of workers, the threshold match value for employment is low and they are most likely to fall back to unemployment for a wide range of negative match-level shocks.

of the model are match-level risk, match heterogeneity, between-group variance, and individual-level productivity risk. A larger fraction of match-level shocks are permanent for workers with more years of experience. For instance, among low-education men, the fractions of match-level shocks that are ex-post permanent at the end of year 2 and year 8 are 39.1% and 69.3%, respectively.

I showed that job mobility is a valuable channel in response to the match-level wage shocks in early careers. The value is particularly large for individuals at the bottom of the job ladder (holding individual productivity fixed) and individuals of low productivity (holding the match quality fixed). The interaction effects between job mobility and unemployment implies that job mobility is less valuable when unemployment income is high and raising unemployment income has less welfare gains in the presence of job mobility. The interaction effects are strongest for the group of workers with low-individual productivity and low match quality. For instance, among low-education men, a more generous unemployment income reduces the value of job mobility for these workers by 18.3% relative to the initial level. Unemployment income also provides some value in terms of reducing the welfare cost of match-level shocks, but only when job mobility is removed from a channel of responding to these shocks.

Recovering the true wage risk facing individuals from their choices is complex. While this paper takes a step to separate match-level risk from individual-level risk by modeling job mobility, it has several limitations that can be extended in future research. First, the modeling of job mobility decisions is simple and highly stylized. For instance, jobs could differ in other aspects besides match quality. Modeling transitions across jobs that differ explicitly in wage risk, return to tenure, or hours of work is desirable and left for future research. Each extension would add another state variable in the model and require a careful specification of the preference structure. Second, in the current paper, productivity of a worker is known to the firm in each period. Empirical work on the implications of learning for wage dynamics within and across jobs and for job mobility is a promising area for future research. This will provide some structural interpretation of the match-level wage shocks that are considered important in this paper (Farber and Gibbons, 1996). Finally, an important avenue for future research is to analyze the relation between job mobility and other channels that workers can rely on in response to labor market risks, and to quantify their relative value in reacting against different types of shocks.

Table 1: Summary Statistics, SIPP 1996

Variable	Mean	Standard Deviation
<i>Demographics</i>		
Age	27.40	2.46
White	0.72	0.45
Some college or more	0.55	0.50
Metropolitan	0.83	0.38
Own a house	0.49	0.50
Married	0.54	0.50
<i>Labor market variables</i>		
Wages	11.62	5.35
Hours of work per week	42.11	11.32
Proportion of job-job transition	0.10	0.30
Elapsed job duration in the first observation period	5.45	5.74
Total number of observations	13544	

Note: Wages are deflated using monthly CPI-Urban (CPI=1 in 1996:1) and averaged over a four-month period (per wave).

Table 2: Total Number of Job Changes (in percentages), by Potential Experience

	Number of job changes				
	0	1	2	3	4+
<i>Quartiles of initial life-cycle period</i>					
Less than 25th (1-4)	45.0	31.7	13.7	5.1	4.4
25-50 (7-10)	54.9	24.0	14.4	4.9	1.9
50-75 (13-16)	59.2	25.1	11.8	2.9	1.0
More than 75th (19-22)	69.2	20.2	8.2	2.4	0.0
Total	56.4	25.6	12.2	3.9	1.95

Table 3: Job Mobility and Wage Changes

	(1)	(2)	(3)	(4)
Within-job wage growth	-0.034** (0.013)	-0.035** (0.014)	-0.028** (0.011)	-0.983** (0.443)
Within-job average wage	-0.082*** (0.009)	-0.717*** (0.090)	-	-
Fixed effects included	No	Individual	Match	Match
Model	OLS	FE	FE	FE-Logit
Observations	8638	8638	8638	1743

Note: *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$. Within-job wage growth is measured in period t . The dependent variable is a job change indicator in period $t + 1$ (equals to one if a job change occurs). All regressions control for year dummies and a quadratic in age. Standard errors (in parentheses) are clustered by person. See Section 3 for details.

Table 4: Estimated Model Parameters

	Low-education	High-education
	(1)	(2)
<i>Labor market shocks</i>		
$\sigma_\eta^2 \times 10$	0.052 (0.008)	0.039 (0.007)

High-education men	0.133	0.093	0.062

Table 7: Value of Job Mobility in Response to Match-level Wage Shocks

Wage components (individual, match)	Baseline	Expand	Reduce cost of search	
		UI	Unemployment	On-the-job
	(1)	(2)	(3)	(4)
<i>Panel A: Low-education men</i>				
u^L, a^L	0.581	-0.107	-0.008	0.023
u^H, a^L	0.638	-0.001	0.000	0.019
u^L, a^H	0.097	-0.011	-0.001	0.005
u^H, a^H	0.104	0.000	0.000	0.004
<i>Panel B: High-education men</i>				
u^L, a^L	0.579	-0.118	-0.016	0.012
u^H, a^L	0.675	-0.017	-0.001	0.009
u^L, a^H	0.166	-0.013	-0.003	0.004
u^H, a^H	0.179	-0.001	0.000	0.003

Note: u^L (a^L) and u^H (a^H) are, respectively, the individual (match) component of wage at the 10th and 90th percentiles in period 12 of the model. Columns (2) to (4) report differences relative to column (1).

Table 8: Welfare Cost of Match-level Wage Shocks

Wage components (individual, match)	Baseline	Job mobility	Expand UI	Interaction effects JM+UI expansion
	(1)	(2)	(3)	(4)
<i>Panel A: Low-education men</i>				
u^L, a^L	0.538	-0.313	-0.110	0.109
u^H, a^L	0.622	-0.396	-0.002	0.002
u^L, a^H	0.991	-0.097	-0.012	0.012
u^H, a^H	0.999	-0.104	0.000	0.000
<i>Panel B: High-education men</i>				
u^L, a^L	0.442	-0.256	-0.097	0.097
u^H, a^L	0.575	-0.388	-0.029	0.028
u^L, a^H	0.980	-0.163	-0.015	0.015
u^H, a^H	0.995	-0.179	-0.002	0.002

Note: u^L (a^L) and u^H (a^H) are, respectively, the individual (match) component of wage at the 10th and 90th percentiles in period 12 of the model. Columns (2) to (3) report differences relative to column (1). Column (4) reports the interaction effects of job mobility and UI expansion. (2)+(4) refers to the value of job mobility in the presence of UI expansion. (3)+(4) refers to the value of additional unemployment benefits in the presence of job mobility. See Section 6.2 for details.

Figure 1: Match-specific Wages and Job Mobility

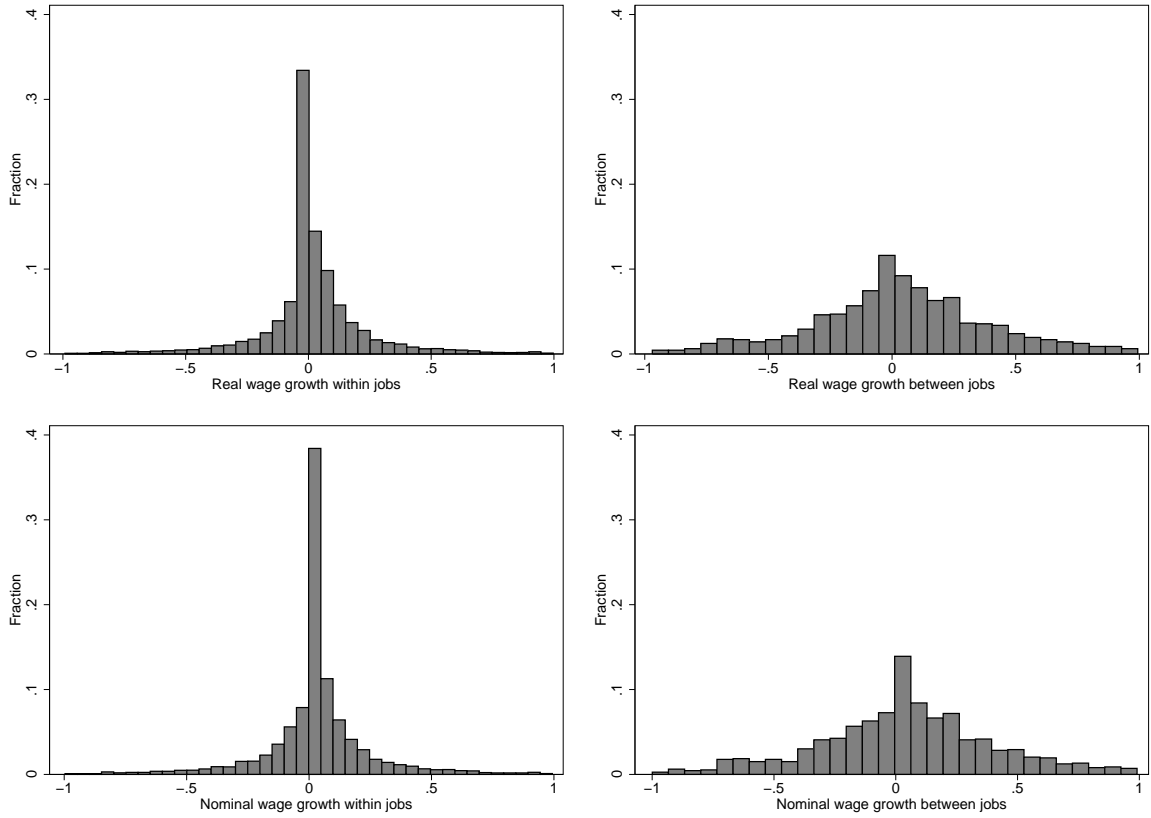

Figure 2: Distributions of Within- and Between-job Log Wage Changes

Note: The top two figures show the distribution of real log wage growth between waves within (left) and between jobs (right). The means (standard deviations) are 0.018(0.24) and 0.052(0.45), respectively. The bottom two figures show the distribution of nominal log wage growth between waves within (left) and between jobs (right). The means (standard deviations) are 0.024(0.24) and 0.059(0.45), respectively.

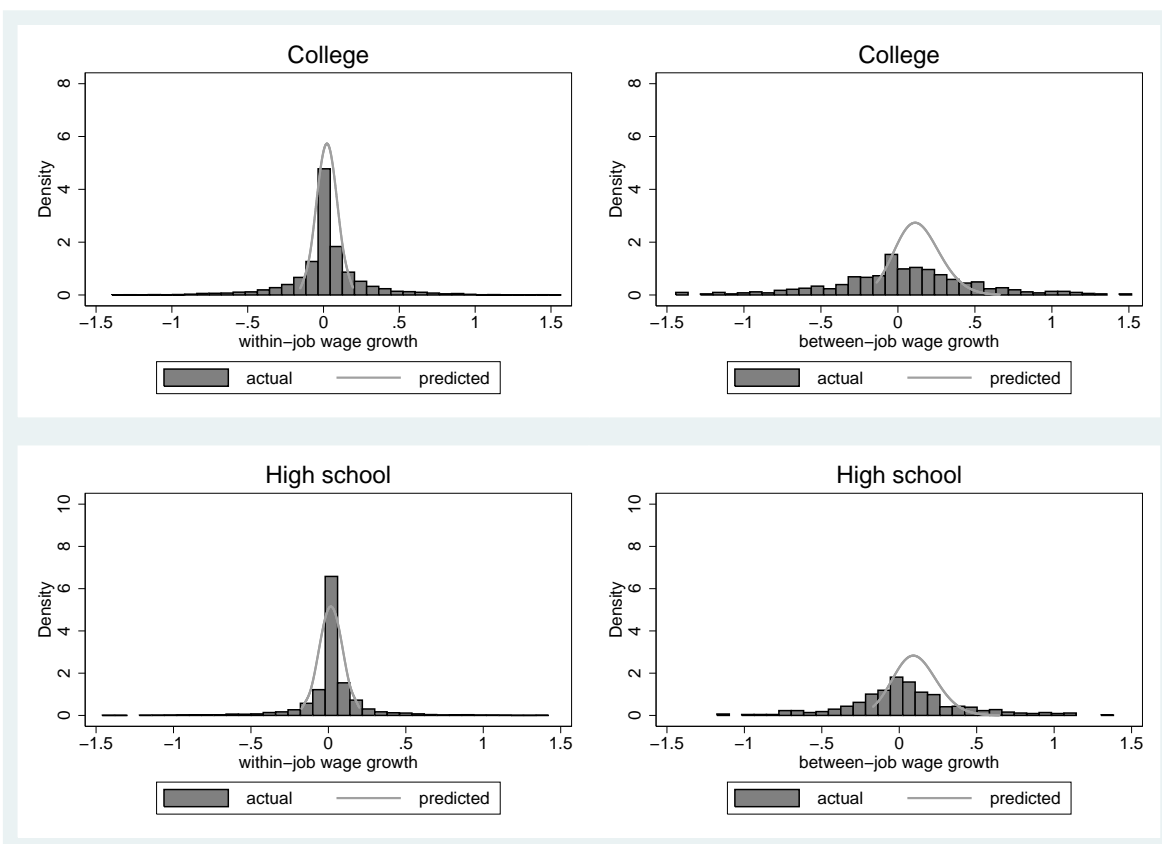

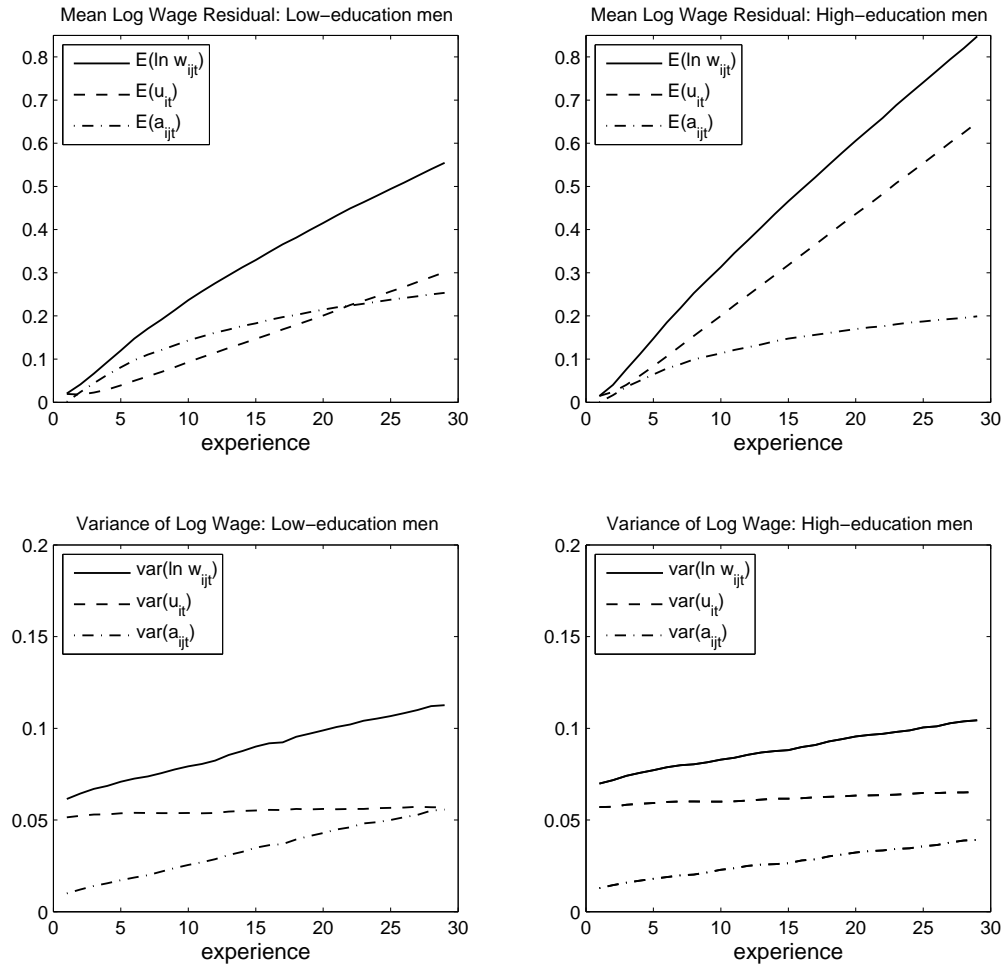

Figure 6: Decomposing Wage Growth and Inequality

Online Appendix to “Wage Risk and the Value of Job Mobility in Early Employment Careers”, by Kai Liu. October 2017

A Approximating the Value Function

I choose to specify a terminal value function at time T_0 and solve the model backwards from T_0 . The assumption at $t = T_0$ is that job mobility and employment decision cease and there are no match-level and individual-level wage shocks from $T_0 + 1$ until the end of work life T . I set $T = 50$ periods and $T_0 = 35$ periods (one period corresponds to four months in the data).

The value function is solved at each combination of unobserved heterogeneity (α_i). The computational burden from solving the value function arises primarily from the continuous and serially correlated state variables u_{it} and a_{ijt} . The difficulty is that, in order to evaluate value function at t , it is necessary to compute the value function for every possible value of a_{ijt+1} and u_{it+1} which may arise in $t + 1$. The number of possible values grows exponentially with t , making computation quickly infeasible. To circumvent this issue, I use an interpolation method developed in Bound, Stinebrickner, and Waidmann (2010). The method involves two steps. In the first step, I determine the range of possible values of a_{ijt} and u_{it} which could arise from simulations used to approximate the value function and evaluate the moments in every period $t = 1, \dots, T_0$. In the second step, the value function is solved backwards. At each time t , the value function is evaluated at 30 equally spaced grid point a_{ijt}^n and u_{it}^n . To calculate the value function at each grid point at time t , I need to calculate the value function at $t + 1$ for possible values of a_{ijt+1} and u_{it+1} . These values will not correspond to the grid points in $t + 1$ in general. At these points, the value function is evaluated by interpolation. For instance, each of the possible value functions at a_{ijt+1} is approximated by interpolating between the two value functions associated with two surrounding grid points a_{ijt+1}^{n-1} and a_{ijt+1}^n .

B Estimation by the Method of Simulated Moments

For any two sample periods p_1 and p_2 such that $1 \leq p_1 \leq p_2 \leq P$ (where P denotes the last sample period), the vector of simulated moments is:

$$\mathbf{g}(\theta; p_1, p_2) = \mathbf{s}(p_1, p_2) - \frac{1}{N} \sum_{i=1}^N f(\theta; \tau_i, p_1, p_2) \quad (1)$$

where N is the number of workers in the panel, \mathbf{s} is a vector of empirical moments implied by the data, and $\frac{1}{N} \sum_{i=1}^N f(\theta; \tau_i, p_1, p_2)$ is a vector of corresponding moments predicted by the model.¹ The empirical moments include the following:

$$\begin{aligned} &E(M_{ip_2} | P_{ip_2} = 1), E(\ln w_{ip_2} | P_{ip_2} = 1), E(P_{ip_2}), E(P_{ip_2} = 0 | P_{i,p_2-1} = 1), \\ &\text{cov}(\ln w_{ip_1}, \ln w_{ip_2} | P_{ip_1} = 1, P_{ip_2} = 1), \text{cov}(M_{ip_1}, M_{ip_2} | P_{ip_1} = 1, P_{ip_2} = 1), \\ &\text{cov}(\ln w_{ip_1}, M_{ip_2} | P_{ip_1} = 1, P_{ip_2} = 1), \text{cov}(M_{ip_1}, \ln w_{ip_2} | P_{ip_1} = 1, P_{ip_2} = 1) \end{aligned}$$

The function f cannot be computed analytically because, in the presence of endogenous selection on the match process, the distribution of the state variables at any given life period does not carry an

¹It is important to note that the predicted moment f depends on τ_i (life-cycle period in the first sampling period). τ_i , p_1 and p_2 map into two unique life periods t_1 and t_2 .

analytical form. I choose to approximate it by its simulated counterpart:

$$\hat{f}(\theta; \tau_i, p_1, p_2) = \frac{1}{S} \sum_{s=1}^S f(\theta; \hat{\nu}_s, \tau_i, p_1, p_2) \rightarrow f(\theta; \tau_i, p_1, p_2) \quad (2)$$

where $\{\hat{\nu}_s\}_{s=1}^S$ is a sequence of random variables that are identically and independently distributed. It consists of sequences of draws of job offers, shocks to match- and individual-specific components from the beginning of the life cycle, and a vector of person-specific unobserved heterogeneity \mathbf{S}_i drawn at the beginning of each simulated path.² With $\hat{\nu}$, the model is able to simulate S employment histories for each individual from the beginning of the life cycle. Twenty simulations per individual are conducted. The observations prior to period τ_i are discarded such that the distribution of τ_i in the simulated sample matches the distribution in the real data. The mean of elapsed job tenure when a worker is first observed in the sample is added to the set of moments to match. The predicted moments are evaluated using simulated data containing $N \times S$ simulated paths, each of which spans P periods.

Let $\mathbf{g}(\theta)$ be a vector consisting $\mathbf{g}(\theta; p_1, p_2)$ at all possible combinations of p_1 and p_2 . The size of vector $\mathbf{g}(\theta)$ is $M \times 1$. The goal of the MSM estimation is to find θ which minimizes:

$$\mathbf{g}(\theta)' \mathbf{g}(\theta) \quad (3)$$

To obtain standard errors, I define conformably the individual vector, \mathbf{g}_i and the corresponding residuals, $\mathbf{e}_i = \mathbf{g}_i - \mathbf{g}(\theta)$. The variance-covariance matrix of $\mathbf{g}(\theta)$ is³:

$$V = \sum_{i=1}^N (\mathbf{e}_i \mathbf{e}_i') \quad (4)$$

and the standard errors are given by

$$\text{var}(\hat{\theta}) = (G'G)^{-1} G'VG(G'G)^{-1} \quad (5)$$

where $G = \frac{\partial f(\theta)}{\partial \theta} |_{\theta=\hat{\theta}}$ is the Jacobian matrix evaluated at the estimated parameters $\hat{\theta}$.⁴

C Quarterly Shocks and Dynamics of Annual Wages

The wage process in this paper is estimated using quarterly (four months) data. Most of the existing estimates of wage risks use annual data. In this Section, I derive the relation between the variance of quarterly wage shocks and the variance of annual wage shocks, using a canonical wage process specified on quarterly data.

In year τ , denote the first four-month period as t , the second four-month period as $t + 1$, and the third four-month period as $t + 2$. For a given individual i , the measured growth in log annual wage

²The normally distributed random variables are constructed through the inversion method. That is, I first draw a vector of random variables z from a uniform (0,1) distribution. Evaluating the inverse of cumulative normal distribution $F^{-1}(z)$ yields a vector of normally distributed random variables. The uniform draws z are held fixed and independent of model parameters. This guarantees that the MSM objective function varies only with respect to changes in parameters of interest.

³Each individual in our data set contributes to only a subset of the moments, because, for example, wages and job mobility are only defined for workers. The notation in the equation below leaves it implicit.

⁴Also see Moffitt and Gottschalk (1995) and Blundell, Pistaferri, and Preston (2008) for a discussion about standard errors in this type of models.

$(\Delta \log w_{i\tau})$ can be written as:⁵

$$\Delta \log w_{i\tau} = \log(w_{it} + w_{it+1} + w_{it+2}) - \log(w_{it-1} + w_{it-2} + w_{it-3}) \quad (6)$$

Suppose that the quarterly wage evolves stochastically with serially uncorrelated transitory component and a random walk permanent component, where

$$\ln w_{it} = \beta_0 + u_{it} + v_{it} \quad (7)$$

$$u_{it+1} = u_{it} + \zeta_{it+1} \quad (8)$$

where ζ and v are quarterly permanent and transitory shocks, respectively. They are assumed i.i.d with means equal to zero. Given the wage process, the change in log annual wage can be written as a function of quarterly wage shocks:

$$\Delta \log w_{i\tau} = \log\left(\sum_{a=t}^{t+2} e^{\sum_{s=t-3}^a \zeta_{is} + v_{ia}}\right) - \log\left(\sum_{a=t-3}^{t-1} e^{\sum_{s=t-3}^a \zeta_{is} + v_{ia}}\right) \equiv g(\boldsymbol{\theta}) \quad (9)$$

where $\boldsymbol{\theta} = (\{\zeta_s\}_{s=t-3}^{t+2}, \{v_s\}_{s=t-3}^{t+2})$. I approximate $g(\boldsymbol{\theta})$ by multivariate Taylor expansion around $E(\boldsymbol{\theta}) = 0$. Then,

$$\text{var}(g(\boldsymbol{\theta})) = \sum_{i=1}^N g'_i(0)^2 \text{var}(\theta_i) + 2 \sum_{i>j} g'_i(0) g'_j(0) \text{cov}(\theta_i, \theta_j) \quad (10)$$

where N is the length of the vector $\boldsymbol{\theta}$, θ_i is the i^{th} element in $\boldsymbol{\theta}$, and $g'_i(0) = \frac{\partial g(\boldsymbol{\theta})}{\partial \theta_i} \big|_{\theta_1=0, \dots, \theta_N=0}$. By assumption, $\text{cov}(\theta_i, \theta_j) = 0$ for all $i \neq j$. Then, the variance of annual wage growth is

$$\text{var}(\Delta \log w_{i\tau}) = \frac{19}{9} \sigma_\zeta^2 + \frac{6}{9} \sigma_v^2 \quad (11)$$

If the same wage process is imposed on annual data, the variance of annual wage growth is

$$\text{var}(\Delta \log w_{i\tau}) = \widehat{\sigma}_\zeta^2 + 2\widehat{\sigma}_v^2 \quad (12)$$

where $\widehat{\sigma}_\zeta^2$ and $\widehat{\sigma}_v^2$ are the variance of annual permanent and transitory wage shocks. From equations (11) and (12), we obtain the relationship between quarterly wage shocks and annual wage shocks as

$$\widehat{\sigma}_\zeta^2 = \frac{19}{9} \sigma_\zeta^2 \quad (13)$$

$$\widehat{\sigma}_v^2 = \frac{1}{3} \sigma_v^2 \quad (14)$$

Therefore, in terms of contributions to the variance of annual wage shocks, the variance of quarterly permanent shocks have a larger weight (by a factor over 6) than the variance of quarterly transitory shocks.

⁵For simplicity, I assume that hours of work do not vary within a given year.

D Alternative Models of Wage Processes

Constant Match Quality. In this alternative model of wage process, match quality is held fixed within each job spell. The life-cycle wage process for the individual i employed by firm j in period t is:

$$\ln \tilde{w}_{ijt} = \ln w_{ijt} + v_{it} \quad (15)$$

$$\ln w_{ijt} = \beta_0 + a_{ijt} + u_{it} \quad (16)$$

$$a_{ijt+1} = \begin{cases} a_{ijt}, & \text{if no job change between } t \text{ and } t+1 \\ a_{ij't+1}^o, & \text{if there is job change between } t \text{ and } t+1 \end{cases}$$

$$u_{it+1} = u_{it} + \delta + \zeta_{it+1} \quad (17)$$

$$a_{ij't+1}^o \sim N(0, \sigma_{a_0}^2), u_{i0} \sim N(0, \sigma_{u_0}^2), \zeta_{it} \sim N(0, \sigma_\zeta^2) \quad (18)$$

$$E(v_{it}) = 0, \text{var}(v_{it}) = \sigma_v^2 \quad (19)$$

Exogenous Wages. In this alternative model of wage process, wages are exogenous because selection into/out of employment and different jobs is ignored. The life-cycle wage process for the individual i employed by firm j in period t is:⁶

$$\ln \tilde{w}_{ijt} = \beta_0 + u_{it} + v_{it} \quad (20)$$

$$u_{it+1} = u_{it} + \delta + \zeta_{it+1} \quad (21)$$

$$u_{i0} \sim N(0, \sigma_{u_0}^2), \zeta_{it} \sim N(0, \sigma_\zeta^2) \quad (22)$$

$$E(v_{it}) = 0, \text{var}(v_{it}) = \sigma_v^2 \quad (23)$$

⁶For comparison across different wage processes, the same distributional assumptions are maintained on u_{i0} and ζ_{it} . For identification, the normality assumptions is not necessary for this model because we do not need to adjust for selection bias.

Table A1: Actual and Implied Correlation Coefficient between Within-job Wage Growth and Job Mobility

	Data	Model predictions	
		Match shock	Constant Match
Low-education men	-0.033 (0.000)	-0.049 (0.000)	-0.001 (0.854)
High-education men	-0.031 (0.000)	-0.024 (0.000)	-0.003 (0.291)

Note: This table reports the actual and predicted (Pearson) correlation coefficient between within-job wage growth in period t and job mobility in period $t + 1$. P-values are in parentheses.
